THE TREATMENT OF ACUTE AND CHRONIC PROTEIN DEFICIENCIES

Collective Review

ABRAHAM O WILENSKY M.D. F.A.C.S., New York New York

IN a recent communication (24) the subject of hypoproteinemia was extensively reviewed and discussed. The conclusions arrived at can be summarized as follows:

The role of the proteins or their derivatives (amino acids, peptides and others) in the human economy is of paramount importance. Besides being the most important structural constituent of all of the body tissues, proteins enter into part or all of the structure of the various enzymes (pepsin, trypsin, and others) hormones (insulin pituitary and parathyroid hormones, and others), and the various antibodies (modified serumglobulins).

During conditions of health and illness, the protein metabolic function and its daily regulation depends primarily upon good liver function. Normally the plasma protein level of the blood bears an approximately constant relationship to the fixed tissue protein supplies in the body and both of these are guarded against ordinary and excessive demands by the large hidden reserve supplies of protein in the various organs and tissues of the body.

Protein replacement in general takes place from ingested food. Plasma proteins are renewed constantly from the reserve stores of plasma protein building material as well as from newly ingested amino acids. Not only the quantity but also the quality of the food proteins is of the utmost importance in the production and regeneration of the various plasma and tissue proteins.

In the light of present evidence it would seem that plasma, tissue, and reserve proteins do not remain static after being elaborated, but rather participate in a dynamic equilibrium as suggested by Madden and Whipple (12) and that the nor-

mal balance results from the continuous ebb and flow between the old and the new in the continuation of the normal metabolic activity.

The food supply of protein furnishes the material for the regeneration of all of the protein fractions in the total plasma protein—albumin globulins, fibrinogen, and prothrombin. After the amino acids (resulting from the hydrolytic digestion of the food protein) reach the liver by the portal vein, they are built partly into proteins and partly into plasma protein building material. A portion of this synthesized material is placed in the reserve store of proteins. In these reserves are placed the precursors of the plasma proteins, although a portion is stored as fully formed protein which is then available instantly in times of stress. It is apparent, therefore, that the cycle of plasma protein formation revolves around the liver both from the viewpoint of formation and from that of storage.

PLASMA PROTEIN DETERMINATIONS

The presence of continued low plasma protein concentrations should be taken as a clinical indication of a profound nutritional disturbance and of a general metabolic deficiency disease. This may be a primary condition, or may be secondary to serious disease especially of the liver parenchyma. Any manifestation may, therefore, be either the cause or the result of this abnormality and commonly both of these effects become intertwined clinically. Specifically this has special reference to the albumin and globulin fractions of the total plasma protein in general cases of hypoproteinemia (undernutrition) and to the fibrinogen and prothrombin fractions in sharply defined

activities relating to the blood clotting materials and function.

The importance of plasma protein estimations for clinical purposes lies in the fact that they can be measured. In making these determinations, however one must take account of any accompanying state of dehydration or hemoconcentration as this tends to give abnormally high values, or of any state of excessive blood hydration which would decrease the relative total serum protein content. Estimations of the total plasma protein concentration in the blood may not indicate the true status inasmuch as a diminution of the serum albumin fraction may coexist with a corresponding increase of the serum globulin fraction. For this reason, blood-volume and albumin-globulin-partition studies are necessary in each case because the total plasma protein contents may not be correctly indicated by the concentration per unit measure of blood. In any event, plasma changes are clinically demonstrable only when the reserve supplies of protein are sufficiently compromised. In general, the amino-acid content of the tissues is about ten times as great as that of the blood plasma. We do not have accurate knowledge of what proportion the hidden reserves of protein-building material bear to either one of the latter. But it must be very large indeed because changes in total serum protein do not occur until the body weight is appreciably compromised, except after severe hemorrhage, traumatic shock, burns, and so on.

In clinical practice a single determination is not of much value. However a succession of repeated observations is immensely valuable because it reveals the course of the disturbance through the deterioration or improvement, primarily, of the protein function and secondarily of any liver cell damage. When repeated in a series, quantitative estimations of any protein deficiencies, and their progression or retrogression, give valuable information concerning the state of function of the liver parenchymal cell or of the deficiency in general and enable fairly accurate prognostications. So that when the deterioration of function, as indicated by the repeated tests, indicates a progressive diminution or when the grade of deficiency is very extreme, these laboratory determinations act as important criteria for determining the immediate advisability of any contemplated operation, the choice of an anesthetic, or the method of operative procedure. In some cases, they suggest efforts to improve the disabling factor and operation must then be postponed until the disability is removed or sufficiently improved. In still other cases, they establish the irreversibility of the

already existing damage, and, when this is sufficiently far advanced they contraindicate conclusively any operation of an elective nature.

In a general way the laboratory demonstration of hypoproteinemic states with or without a coincident loss of body weight indicates some interference with liver cell function. But inasmuch as the method of production of this deficiency varies, there can be no assumption of intrinsic liver disease, except as it corroborates one's diagnosis on other more appropriate and reliable criteria. Nevertheless, even for this purpose, repeated determinations are valuable as corroborating proofs of liver cell damage, when all other clinical and laboratory findings point definitely to the liver as the essential seat of the disease, and, to a lesser extent, when latent disease is suspected.

CLASSIFICATION OF HYPOPROTEINEMIAS

In accordance with the basic production mechanism of hypoproteinemia, one can distinguish three types (Davis and Getsoff 5) of this general protein deficiency:

1. Hypoproteinemia of the prehepatic type which is caused by interference with adequate nutrition intake, digestion, or absorption of plasma protein-building materials, without any disturbance of the ability of the liver to form plasma proteins as the supply of protein-building material is inadequate. This is the most general and important cause of hypoproteinemia.

2. Hypoproteinemia of the hepatic type, which results from the inability of the liver itself to build plasma proteins, despite the fact that adequate supplies of plasma protein-building material are received. In most of the reported cases, this is accompanied by other evidences of a reduction of liver function in the presence of apparent liver disease. A similar effect is demonstrable in latent hepatic disease also.

3. In the posthepatic hypoproteinemia, there is an adequate formation of plasma proteins by the liver but an abnormal amount of plasma proteins is lost, for example, (a) in repeated bouts of, or in a severe, diarrhea (b) in excessive albuminurias (nephroses) (c) following a large hemorrhage (d) accompanying any outpouring of serum in any hollow cavity (pleural effusion peritoneal ascites, or peritoneal exudation) and (e) following the exudation of serum in large traumatic areas (burns). This form is often combined with under nutrition (group 1).

CLINICAL DISTRIBUTION OF HYPOPROTEINEMIA

Various grades of hypoproteinemia have been clinically observed in many abnormal states and

in many forms of disease. In undernourished and otherwise apparently healthy individuals, the protein reserves become dissipated and exist at abnormally low levels without any subjective or objective manifestations. The compensatory mechanism is sufficient to make good the ordinary wear and tear of the tissues up to a certain point and there may be no laboratory or other method of determining the state of the protein reserves. However upon the appearance of any undue strain—illness, anesthesia operation—this deficiency may become clinically perceptible, and frequently be demonstrable by laboratory means if it is not already apparent clinically.

Hypoproteinemia of this (prehepatic) type occurs in periods of famine (in India China) during wars (the first World War) as a consequence of individual whims in dieting (vegetable diets and so on) in alcoholics, often in pregnant women who do not take sufficient nourishment, and both before and after operation in malnourished individuals.

In industrial practice. Fatigue is, probably the most important form and cause of disability in the industrial worker. It is an important factor because it spells decreased and/or faulty production either for the individual himself or because of his deficiencies, for his fellow workers when he is engaged in team work. Any extraordinary form of fatigue or its undue prolongation should immediately arouse suspicion that some underlying disturbance is present. Two factors operate to bring this situation about (1) sufficiently severe malnutrition and (2) any form of latent disease especially of the liver. Under these conditions a state of protein deficiency and hypoproteinemia results, the symptoms of which include (1) loss of weight and strength (2) loss of stamina or pep (3) various degrees of chronic fatigue (4) a much lessened resistance to other varieties of infections and disease and (5) deficient healing power in any industrial and/or other trauma. At the same time these symptoms are the earliest manifestations of latent hepatic disease. In many cases all of these factors became involved in a vicious circle and the one aids abets and intensifies the others and their effects.

Any industrial worker showing any of these manifestations should immediately be examined for any possible state of protein deficiency or hypoproteinemia, and for the possible presence of any associated latent liver disease.

In military practice. No matter how well soldiers are fed behind the front lines, nutrition is very apt to deteriorate under combat conditions. Frequently the men are under "starvation" condi-

tions. There is decreased general resistance to any extraordinary episode or trauma, and the general condition is not what an active soldier should possess. In previous wars, the healing of wounds was notoriously behind that seen in civil practice. There is loss of weight and protein deficiencies are undoubtedly common. The fact that plasma transfusions have done such wonders for the wounded in this war only goes to show that plasma furnishes much ready protein for the injured soldier. Acute protein deficiencies are a feature of the extensive burns which present battle practice and methods have caused to a much larger extent than any previous war. It is to be remembered how important an enriched protein diet is for all the wounded otherwise disabled and convalescing soldiers in all evacuation and home hospitals.

In traumatic conditions. Acute and subacute protein deficiencies occur in association with extensive traumatic conditions large suppurating wounds, severe infections, and especially burns. In the latter the protein deficiency corresponds to the extent of the burned area and when the latter is large, the protein loss attains extraordinary amounts.

Nutritional edema. Occasionally one sees patients who have general (subcutaneous serous cavity) edema without evidence of the usual forms of pathology which produce such waterlogging. They have no elicitable manifestations pointing to nephritis hypertension cardiac disease cirrhosis myxedema or a malignant growth.

We have come to know that these patients have moderate or excessive degrees of hypoproteinemia sometimes as low as 4.5 gm. per cent of total serum protein. There is reason to believe that an underlying liver parenchymal disease is present and they improve when adequate supplies of protein are provided. For want of a better name their condition has been included under the general term of "nutritional edema."

Starling ('0) was the first to call attention to the part played by the osmotic pressure of serum proteins in regulating the interchange of fluid between the blood stream and the tissues.

The Starling hypothesis has helped to explain these clinical conditions. Sufficient available protein helps to maintain a normal colloidal osmotic pressure in the blood stream and in the capillary bed. Protein deficiencies are now thought to disturb the physicochemical conditions to the extent that water is retained in the body tissues with the formation of edematous areas and in the hollow spaces with the accumulation of edema fluid. This change causes more or less reduction in the amount of urine secreted, causes states of hemoco-

tion, and facilitates pseudo-obstructive manifestations. Nutritional edema and the otherwise obscure accumulations of fluid in the hollow spaces and cavities are only understood on this basis.

Occasionally similar forms of general edema occur when the total serum protein level is apparently in the normal range. In these seemingly paradoxical cases, it is found that the albumin concentration is low and that the globulin concentrations are increased, that because the osmotic pressure of the globulin fraction is much lower than that of the albumin fraction, there is a lower total osmotic pressure and that this disturbed physicochemical relationship permits fluid to accumulate in the tissues and hollow spaces.

Hypoproteinemia with other differentiated forms of disease. In clinically established disease, protein deficiency including lessening of the normal reserve occurs in any basic condition of undernourishment (from insufficient diet to actual starvation, in prolonged vomiting and so on) in any condition associated with loss of digestive capacity (disease of the stomach, pancreas) in any condition associated with decreased intestinal absorption with or without increased alimentary-tract elimination (the various diarrheas and dysenteries).

Hypoproteinemic states are found in all varieties of established or latent liver diseases (atrophic and hypertrophic cirrhosis, the various forms of acute and subacute yellow atrophy, biliary cholelithiasis, acute and chronic cholangitis in gross and capillary forms) after burns of the body in luetic, tuberculous, and malignant disease of the liver, in all forms of traumatic, toxic, and/or chemical injury of the liver and in the destruction accompanying liver suppuration (Johansen, 11; Thompson, McQuarrie, and Bell, 21; Casten, Bodenheimer and Barham, 3).

In severe thyrotoxic disease, two factors operate to produce protein deficiency (1) an associated parenchymal lesion in the liver and (2) the increased catabolism of protein due to the generally increased metabolic activity as shown by the high metabolic rate. The importance of this is becoming more and more generally known.

Protein deficiency also occurs in renal conditions (nephroses) in which albuminuria is an important factor. In certain severe conditions accompanied by excessive loss of nitrogen due to abnormal destruction of tissue, there are large losses of nitrogen in the urinary output, and the tissue and reserve stores of protein become abnormally depleted. Frequently too, this loss is enhanced by the inability to take and absorb nutrition for replacement purposes. Protein deficiency is also found in the malnutrition accompanying

the wasting of any chronic disease (malignancy, tuberculosis) and very often in association with various grades of anemia.¹

POSTOPERATIVE HYPOPROTEINEMIA

A state of negative nitrogen balance exists for varying periods after operation. The important factors include (1) anesthesia (2) a major surgical procedure with operative manipulation of deeply situated viscera and tissues (3) a brief period of starvation (4) shock, fever, vomiting, and the presence of injured tissues. In addition, Cuthbertson (4) has demonstrated appreciable losses of nitrogen after severe and extensive operations as well as after severe injuries. There seemed to be no correlation between age, sex, the presence or absence of malignant neoplasm or other type of disease, and the extent of nitrogen loss.

The adverse effect of general and spinal anesthesia upon the liver cell seems to be increased in hypoproteinemic states, and by the preoperative and postoperative use of drugs of the sulfanilamide group which also have the tendency to increase any destructive effect upon the liver cell.

Various studies have indicated that pulmonary complications occur much more frequently in elderly malnourished subjects than in others. In these persons the usual hypoproteinemias which occur and are expected after severe abdominal operations seem much more increased.

The major portion of the protein loss occurs during the first four or five days after operation during which time food is not permitted at all, or only in limited quantities and, ordinarily, this seems to be the most important factor. Since this brief period of protein deprivation or limitation is well tolerated, the vast majority of patients recover without any special attention to the temporary abnormality of the nitrogen balance, and the hypoproteinemia is made good directly after the return to full diet. However the diet must contain not only protein but also carbohydrate and fat, as nitrogen equilibrium cannot ordinarily be achieved on a pure protein diet.

POSTOPERATIVE ASTHENIA

Quite commonly it has been clinically noted that following major surgical operations of various types, there is frequently a rather prolonged asthenia which is often appreciable for a few

¹There are certain congenital malfunctions of the protein metabolism in which the deficiency is not reflected or recognized in any demonstrable anatomical pathology. The subjects are in apparent good health and the only evidence of any such disorder is an increased secretion of an abnormal urinary constituent, usually an intermediate product in the metabolism of particular body substances. These congenital deficiencies of the protein metabolism, known clinically as cystinosis, alcaptonuria, phenylketonuria, and tyrosinemia, have no relation essentially to the subject under discussion.

weeks or even longer after discharge from the hospital. Leriche has referred to this syndrome which cannot be clearly defined as "maladie postopératoire," and ascribed it to generalized disturbances of the sympathetic nervous system. This form of asthenia has been encountered, perhaps, most often after operation upon the pancreas—pancreatic asthenia (Whipple 23)—and less often upon the gall bladder and liver or after severe destructive disease. Not enough is known concerning all of these forms of postoperative asthenia, and further investigation is necessary. But it is interesting to speculate upon the possible role of any postoperative nitrogen loss in this connection. While the quantity of tissue protein lost may not be large, the source and character of the catabolized protein under these conditions are not known and might conceivably differ from those of the stores depleted. A general hypoproteinemia may result, or there may be a loss of certain reserve protein fractions or of necessary preceding amino acids, when in the course of their usual activities the subjects simply refrain from their customary protein foods and nevertheless continue their normal activities.

Multiplicity and combinations of causal agents and conditions. In many cases, both surgical and medical, more than one cause for the hypoproteinemia is present. There are often associated anemia and avitaminoses.

THE TREATMENT OF CLINICAL HYPOPROTEINEMIA

The preventive treatment of hypoproteinemic states depends to a great degree upon the cause of the deficiency and upon the method of its production. In ordinary states of undernutrition, the essential of therapy is increased and abundant nourishment. In disease of the gastrointestinal tract, this must be combined with rectification of the underlying disease, either an increase of the digestive action or an elimination of abnormally increased bowel evacuations. In hemorrhage, replacement of the lost blood is imperative. In essential disease and/or injury of the liver parenchyma, removal of the cause (chemical or other poisoning, deficient food with and without deficient vitamin supply) must be accomplished. In thyrotoxic disease, lowering of the basal metabolic rate with drugs (iodine, thiouracil and others) or by subtotal thyroidectomy with or without preceding medication is necessary. In renal nephroses and albuminurias, the kidney condition must be improved, and so on. In mild states of hypoproteinemia, these measures including the proper additional supply of protein foods by mouth will suffice.

In operative cases the assurance of an adequate supply of protein is most important first to protect the liver from the possible toxic effects of anesthesia, second, to prevent tissue edema, which interferes with healing of the wound, and, third, to supply the essential nutrients required for tissue repair and regeneration.

The emphasis which has been placed on correcting dehydration and electrolyte losses before and after operation has often been accompanied by failure to consider the mechanism involved in keeping fluids in the blood vessels (Starling hypothesis). Proper control of the fluid and electrolyte balance in surgical patients receiving parenteral fluids is not possible unless the serum-protein concentration is maintained within normal limits.

If no success follows in the mild cases or it follows in insufficient degree if the grade of the protein deficiency is severe or extreme, or if there is any necessity for urgency in the correction of the hypoproteinemic state, more active measures are necessary including the parenteral replacement of protein. Parenteral replacement of protein can be accomplished by (1) the transfusion of fresh whole blood, (2) the transfusion of wet or dried human plasma, (3) the reinfusion of human transudate fluid (ascitic and/or pleural), and (4) the use of amino acids.

All of these have their distinct place and field of usefulness in therapy and each, or a combination of them, should be selected in any individual case in accordance with the purpose to be accomplished. In any case, an estimation of the good effect which is being accomplished can be obtained from a laboratory standpoint by estimations of the total protein content of the blood plasma and, clinically by evidences of improvement in the general condition of the patient and of any local (operative, traumatic) condition which is present.

1 AND 2. TRANSFUSIONS OF WHOLE BLOOD AND/OR PLASMA

In emergency conditions and/or in any immediate postoperative period transfusions of blood are the most satisfactory method for restoring the protein supply both because of the ease of introduction and because of the rapidity with which results are obtained. Under nonemergency conditions, and in long-standing conditions in which protein replacement therapy must be carried out continuously and for long periods of time, such transfusions are not practicable, except under unusual conditions, both because the supply of blood is necessarily limited and for reasons of cost. When the need for red cells does not exist, excessive whole-blood transfusion can be dangerous

since it may lead to seriously elevated hematocrit values.

When whole blood is, for any reason, not available human plasma forms a most excellent substitute and approaches practically completely fresh whole blood even though at present it suffers from the temporary disadvantages of expense and inadequacy of supply. About 1,000 cc. of plasma are required to raise the protein content of the plasma of the average adult 1 gm. per 100 cc. In severe hypoproteinemia many liters of plasma may be needed. When plasma is given, absorption and synthesis are unnecessary. After liver injuries, burns, and so on plasma transfusions have proved to be life saving.

3 THE REINFUSION OF HUMAN TRANSUDATE FLUID

In the hypoproteinemia accompanying the cirrhoses with ascites, or in nutritional edemas, human transudates may be used. Remarkable results have been obtained the plasma proteins become elevated great diuresis follows and the ascitic fluid may not reform for quite a long time.

The available transudates which can be used are those in the abdomen and those in the pleural cavity. The latter are much the richer in protein content, sometimes averaging as much as 4.5 per cent. ascitic fluid usually contains between 1 and 2.5 per cent, occasionally as much as 4 per cent. Ascitic fluid is usually more abundant. The fluid transudate is obtained by tapping under rigid aseptic control. It is possible and even desirable to pool fluids from more than one source, as in the use of blood plasma. No grouping or typing is necessary. Before use each batch of fluid should be tested bacteriologically and any excess complement can be eliminated by heating the fluid in water both to a temperature of 56° C. for fifteen minutes.

In nutritional edemas and similar conditions, the use of transudate fluid seems especially applicable. In any large center of population, and in any large hospital environment there should be numerous opportunities for securing such fluid in relatively large quantities. The fluid is easily manipulated, no tests are necessary and there is a minimum of danger and little or no reaction.

I know of one case (Simons, 19) in which this method was repeatedly employed for a year or more without temperature or other reaction at any time.

4 THE ADMINISTRATION OF PROPERLY PREPARED AMINO ACIDS (HYDROLYZED CASEIN AND SO FORTH)

Amino acids can keep the body in nitrogen balance, and are much more economical and more

easily obtainable than plasma. Amino acids require no further digestion and are available to the cells immediately after they enter the blood stream.

When protein is eaten it is hydrolyzed into polypeptides and into amino acids of the general formula $R-CH(NH_2)COOH$ by the proteolytic enzymes, pepsin, trypsin and erepsin. The process is very complex. The final digestion of protein takes place in the small intestine and the resulting amino acids and small peptides (?) pass into the blood stream and are circulated throughout the body. Various cells in the body then take up the amino acids and peptides for the synthesis of nitrogen-containing products into proteins and protein-building material.

The usual human diet contains varying amounts of protein from animal and vegetable sources. The nutritive value of any of these depends upon its digestibility its potential amino-acid content, and its content of those individual amino acids (valine and methionine) which have been proved indispensable. The known amino acids are

A. Essential	B. Nonessential
1. Lysine	1. Glycine
2. Tryptophane	2. Alanine
3. Histidine	3. Serine
4. Phenylalanine	4. Norleucine
5. Leucine	5. Aspartic acid
6. Isoleucine	6. Diisotyroline
7. Threonine	7. Proline
8. Methionine	8. Hydroxyproline
9. Valine	9. Thyroxine
10. Arginine	10. Tyrosine
	11. Glutamic acid
	12. Cystine (cysteine)

The essential amino acids must be present in the dietary protein to assure normal growth for the animal organism. The "nonessential" amino acids either may not be required by the body at all, or may more probably be synthesized by the body from other amino acids (Rose, 17). As yet, however little is known of the quantitative requirements of individual amino acids or the function of each in the body.

Of the amino acids listed in column A above, all but histidine and arginine have been found necessary for the maintenance of nitrogen balance in normal adult males. A deficiency of even one of the amino acids that are essential for tissue construction limits the value of a protein to the animal body. A number of the proteins occurring in foods are deficient in one or more of the essential amino acids.

For example, diets which consist mostly of milk are insufficient for maintenance as shown by bed-

ade experience in postoperative cases, while gelatin, although rich in glycine (an amino acid that may be synthesized by the body) does not contain tryptophane and valine (essential amino acids) nor tyrosine which is nonessential. The amino acids in fish and meat measure up very favorably with the as yet unknown requirements for normal maintenance and growth. Generally speaking animal proteins contain all or nearly all of the essential amino acids, but vegetable proteins do not. However one can obtain similar end-results and effects by supplementing the various vegetable proteins with one another, and with or without the supplementation of an amino-acid mixture until the total amount is adequate. Under such circumstances, animal proteins are not absolutely necessary. Customarily however human beings prefer a diet containing a large amount (more than half) of the protein from animal sources. In any case, the plasma proteins can be synthesized only if the body receives the proper mixtures of amino acids.

In any condition in which surgical shock is a factor amino acids¹ find no place because they are foods and when they are injected into the circulation they are taken up quickly by the body cells and removed from the blood stream. Under such conditions, blood and plasma are preferable, because they stay in the circulating blood and raise the osmotic pressure and the volume of the blood.

The administration of amino acids is especially indicated when the need for replacement protein therapy extends over an appreciable length of time: less frequently as an exclusive means and very much more frequently as an adjuvant method in addition to the ordinary food intake of the individual. Here the oral administration of amino acids finds its special field.

a. The administration of amino acids by the oral route. It has been shown conclusively that a mixture containing all the essential amino acids can be given orally that, when so administered, the amino acids are rapidly absorbed from the gastrointestinal tract that in this manner they may be substituted for food protein that by this means a patient may be kept in nitrogenous equilibrium and that no untoward effects occur or follow. If such a mixture is given in relatively large quantities, however it is sometimes irritating.

b. The administration of amino acids by the intravenous route. The possibility of supplying protein parenterally with amino acids was done

experimentally as early as 1913 by Henriques and Andersen (10) and has since been suggested for clinical use by others, particularly by Rose (16) in 1934.

The intravenous administration of amino acids has been employed by Elman (6, 7) Farr and MacFadyen (8) Shohl and associates (18) Whipple and associates (22) by myself, and by others. Theoretically the method is good, but it presents several practical difficulties, not the least of which is the preparation of a standardized hydrolysate which is safe for intravenous use.

The earlier difficulties have largely disappeared with successive improvements in the manufacture of a proper hydrolyzed casein which so far has been found to be the best source of material. The solubility has increased so that a perfectly clear solution can be administered intravenously with minimum danger of phlebitis when long periods of venoclysis are required. However this danger in any case is not very great with the dilute (2 per cent) solutions.

The most serious difficulty has proved to be the occurrence of occasional febrile reactions (Shohl, 17 Elman 6 and others).

Untoward reactions are due to one or more factors connected with the manufacture of the hydrolyzed casein, with its method of solution and preparation for intravenous use, or with the technique, i. e. the rapidity of the administration itself. Nevertheless, the preparations now available have been administered to many patients without untoward effects by myself and by other observers.

In the experience of Brunschwig, Clark, and Corbin (2) minor disturbances were frequent they included anorexia, mild and occasionally severe nausea and vomiting and a generalized disagreeable flushing sensation. In the exceptional instances these were sufficiently pronounced to warrant discontinuation of the injections after one or several attempts.

It would appear that in certain types of acute hepatitis, a sudden flooding of the circulation with amino acids is too great a physiological load for the liver to tolerate. Nevertheless, postmortem studies of 9 patients who received substantial quantities of casein digest during their terminal disease failed to reveal evidence of toxic effects ascribable to the digesta.

c. The administration of amino acids into the bone marrow. Solutions of amino acids are found to be equally effective when injected into the bone marrow. This method offers a satisfactory way of achieving parenteral injection when the other routes are inaccessible, impossible, or inadvisable.

¹The expensive amino acids will be used here in the sense of soluble mixture of amino acids and other protein-split products derived from the by analytic solution of proteins.

The injection of amino acids into the bone marrow was done intrasternally by Altschuler, Sahyun, Schneider and Satriano (1) with Turkel needles, and it was found that amino acids may be given by this route as rapidly and in as large an amount as by the intravenous route. The results were no different than those with the other methods, but intrasternal administration was advantageous in patients in whom access to the veins was difficult. The Turkel needles may be left in place for twenty four hours or longer and repeated injections may be given through them.

General considerations in intravenous and in intrasternal administration of amino acids. In various conditions patients are able to metabolize from 5 to 30 gm. of protein in the form of amino acids¹ per hour. The average patient is able to take up to 15 gm. per hour and when this is properly given about 95 per cent of it is utilizable. The solution should not be administered any more rapidly than the subject can metabolize it. In order to supply enough carbohydrate simultaneously it is usual and best to give the amino acids in a 5 per cent solution of glucose, either alone or in saline solution. Glucose is usually metabolized at the rate of 0.84 gm. per hour or kilogram of body weight, according to most authorities. Usually large quantities of both amino acids and glucose are required if any good is to be accomplished.

When the paradoxical observation is made that protein concentration is decreasing while the hemoglobin is increasing as fluids are given intravenously one should deduce that plasma is being lost from the blood stream. According to Minot and Blalock (15) the indication, then, is to give increasing amounts of protein, possibly with colloids to increase the osmotic pressure. Very large amounts are needed.

d. Administration of amino acids by the subcutaneous route. When intravenous amino acid is not well tolerated, a 3.3 per cent solution in distilled water may be given safely by hypodermoclysis without discomfort and reaction in the tissues. Patients with clinical icterus, or toxic forms of marked liver damage, as shown by functional tests, commonly have reactions after intravenous injection, but they tolerate hypodermoclyses of the 3.3 per cent solution well.

e. The administration of amino acids by rectum. This has been reported by Griesbach (8), and by McClendon, Cavett and Johnson (13). However the usefulness of the method is questioned by McLester (14) on the ground that rectal feeding is, at best, limited because of the variabilities of

its absorption. I am inclined to agree with the latter statement.

THE MANAGEMENT OF PROTEIN REPLACEMENT THERAPY

a. General considerations

In a few of the cases with chronic protein deficiency it may be found possible to provide an adequate diet which will give not only enough calories, vitamins, minerals, and protein, but an excess of protein to correct any existing protein deficiency. However, the correction by such methods requires considerable time. This method will find its greatest usefulness in the mildest type of case, in the postoperative period in subnormal subjects, and possibly in the cases of postoperative asthenia.

However even in these cases and certainly in all other cases, it is very advisable to reinforce the high-protein diet with amino acids in order to give a maximum amount of protein-building substances. In any case, enough should be provided, if possible, to give a superabundance and this should be supplemented with sufficient carbohydrates and fat.

It usually is possible to feed enough carbohydrates and fat to meet the caloric requirements, and then provide excess protein nutrition by supplementing such proteins as the patient can eat with sufficient quantities of amino acids administered orally.

The amount of protein (including amino acids) administered should be estimated upon the basis of the difference between the nitrogen intake and output of the individual. The amount of total circulating protein is calculated by multiplying the plasma volume by the protein concentration. The amount of other body protein (tissue and reserve protein) is usually estimated to be 30 times the plasma protein. The total nitrogen excretion per day in urine plus feces multiplied by 6.25 will give approximately the amount of protein broken down in the body during the twenty-four hour period.

An intake of protein or amino acids equivalent to the protein destroyed in the body will suffice to keep the body in nitrogen balance, but it will not allow for correction of the tissue protein deficiency or for the raising of the plasma protein level. An additional amount over that required for balance must be given if protein deficiency is to be corrected. Probably the greater the excess, the more rapidly and more efficiently the correction of the deficiency takes place.

The number of calories any one person requires for twenty-four hours for various activities can be

¹One gram *N* equals 6.25 gm. protein.

CHART I.—THE FOOD MINERAL, AND VITAMIN REQUIREMENTS OF AN INDIVIDUAL

(This chart is taken from the recommendations of the Committee on Foods and Nutrition of the National Research Council.)

	Cal- ories	Total Calories Daily Derived from		Cal- cium gm.	Iron mgm.	Vita- min A+ I U	Thia- min mgm.	Ascor- bic Acid mgm.	Ribo- flavin mgm.	Nia- cin mgm.	Vita- min D I U
		Protein	Carbo- hydrate and Fat								
Man (70 kgm.)											
Fully active	3000	240 (70 gm.)	2,760	0.8		5000	1.8	75	2.7	18	
Very active	4500	240 (70 gm.)	4,100				2.3		2.3	23	
Sedentary	2000	240 (70 gm.)	2,760				1.2		2.3	5	
Woman (60 kgm.)											
Fully active	3000	240 (60 gm.)	2,760	0.8		5000	1.5	70	2.7	15	
Very active	3000	240 (60 gm.)	2,760				1.5		2.7	15	
Sedentary	2000	240 (60 gm.)	2,760				1.2		2.7	15	
Pregnancy (latter half)	3000	340 (85 gm.)	2,420	1.5	5	6000	1.5	00	5	18	400-800
Lactation	3000	400 (100 gm.)	2,600	2.0		8000	2.3	30	5	23	400-800
Children 1 to 12 years											
Under 1 year	1000*	3-15 (3-4 gm.)	84*	1.0	6	500	4	30	0.6	4	400-800
1 to 3 years	1000	150 (40 gm.)	1040		7	1000	6	35	0.9	4	
4 to 6 years	1500	200 (50 gm.)	1400		8	1500	8	50	1.3	8	
7 to 9 years	2000	240 (60 gm.)	1760		10	2000	1.0	60	1.9		
10 to 12 years	2500	280 (70 gm.)	2,220	1.5	12	2500	1.2	75	2.3		
Girls

16-20 years	2500	280 (70 gm.)	2,220	1.5	12	2500	1.2	75	2.3		

*Per Kg.

†mgm. Thiamin = 100 I. U.; mgm. ascorbic acid = 10 I. U. (I. U. = U. S. P. unit)

‡Less may be required if provided as vitamins A; greater if chiefly as provitamin carotene

§Infant needs increase from month to month. Ammonia gives are for approximately 16-18 months

¶Amounts of protein and calcium needed are less if from breast milk.

**Vitamin D is not necessary for older children and adults. If not available from sunshine, should be provided probably up to minimal amounts recommended for infants.

††Urverages based on middle age for each group (as 2, 3, 4, etc.) and for moderate activity

‡‡Good formula for the average grown adult would include carbohydrates from 60 to 80 per cent, fat from 5 to 10 per cent, and protein from 30 to 35 per cent plus the necessary vitamins and minerals.

determined with great precision. For a moderately active person, 45 calories per kilogram are adequate for a very active worker 65 calories and for a sedentary worker, 37 calories per kilogram. Soldiers require from 60 to 65 calories. For an active child, the caloric requirement is quite high, and exceeds that of an adult.

The daily protein recommendation for an adult is 1 gm. per kilogram of body weight, i. e., roughly speaking 70 gm. of protein a day for the average man with a body weight of 70 kgm. or 10 per cent of the required 3,000 calories. For children under six years of age, 3 gm. of protein daily per kilogram of body weight are necessary. Children above the age of six should be maintained on 2 1/2 gm. daily per kilogram of body weight until they become adults. Nutritionists, today, are generally agreed that the liberal use of protein in the diet (from 80 to 100 gm. or more, daily) has no deleterious effect either on the kidneys or on the vascular system. On the contrary there is evidence that a high protein diet stimulates vigor and physiological efficiency.

Amino-acids therapy to be effective, must be supplemented with sufficient carbohydrates, fats, minerals, and vitamins, and an abundance of fluid to meet the caloric and all other requirements of the body. Under such conditions, amino acids are free to be manufactured into body proteins. They will do this more effectively if protein food substances are supplied in the diet in addition.

b Protein replacement therapy under specific conditions

With all of these facts in mind, and under proper laboratory estimations of the protein nitrogen balance of the individual, the following rules can be advantageously used under various conditions. As can be seen, the suggestions follow along in the order of intensity of the hypoproteinemia and general protein deficiency. They should be varied as the indication is acute and demands urgency in treatment, as the therapy is necessary to correct a long drawn-out condition as a result of which a chronic hypoproteinemic state has resulted or as the indication arises and either disappears or becomes intensified. It should be understood that

each case is a feeding problem in itself and that the latter gains or loses in importance in accordance with the urgency produced by an advanced state of protein deficiency incident to undernourishment, starvation, or severe gastrointestinal disease by an underlying severe hepatic parenchymatous disease with its resultant nutritional metabolic disturbance or by some extraordinary circumstance, as an operation.

In calculating the daily necessary amount of protein, the following factors must be considered (1) the patient's nitrogen balance (2) the estimated degree of deficiency in the tissue and reserve protein and (3) the possible continuance of the original disability which caused the deficiency if one exists finally an additional amount of protein should be given to allow for any unavoidable error in the computation.

In severe cases one may follow the same rule of thumb that one frequently does with abdominal drainage—whenever in doubt, give more—and in very severe cases one should give as much as possible by every available channel and method up to the limit of tolerance.

In the following conditions, an estimation is made of the daily necessary supply of protein.

In general malnutrition. In early cases of general malnutrition about 2 to 3 times the normal requirement, calculated at the level of 60 calories per kilogram of body weight, should be given. The amount should be increased in accordance with the degree of malnutrition and in advanced stages as much as the patient will tolerate should be given regardless of the calculated estimate.

In anemia. In advanced cases, as much as 25 per cent of the globin protein may be lost. The serum albumin factor seems to be the necessary replacement item. The fact that an anemia is present indicates that the preceding nutritional disturbance has existed for a long time. Hence it is necessary to follow the same rules as in any moderate or advanced case of general malnutrition.

In nephritis and/or nephrosis. The albumin lost daily in the urine is easily calculated. Anywhere from 2 to 3 times the amount lost is necessary to replace the latter and to make good the other factors previously indicated.

In infections. Metabolic activity is so greatly increased during these infections that from 2 to 3 times the normal amount is necessary.

In burns. Losses of one third or more of the plasma are often dissipated daily in very extensive burns. These losses are increased with any added infection or in the presence of high fever. The total catabolic loss may be as high as 250 gm.

per day plus the amount lost by seepage in the burned area. All of these factors are to be taken into account in estimating the necessary replacement supply of protein. But for practical purposes the maximal amount of replacement therapy (anything up to 10 times the normal requirement or the limit of toleration) should be employed and sometimes the amount needed is more than the subject can assimilate.

In alcoholism and in hepatic parenchymatous disease. Both of these can be considered together because the protein replacement therapy for chronic alcoholism is the same as for the prevention of, or the early-stage treatment for parenchymatous disease of the liver.

In all stages the essential disability is that of a severe malnutrition. In moderately advanced and in far advanced conditions, the calculation should include the daily loss of nitrogen, an estimate of the tissue and reserve protein deficiency and a calculation of the amount of protein lost in digestion from the amount administered. Then this should be multiplied several times in order to obtain an exceptionally rich protein diet. In severe cases as much as from 4 to 5 times the calculated normal must be given for a long time before any beneficial result is seen.

In hyperthyroidism. The calculation should include the loss from the extraordinary metabolism due to the disease, plus the deficiency incident to any hepatic parenchymatous disease which is a common complication. The treatment should follow the suggestions given for severe malnutrition plus those for hepatic parenchymatous disease. The nitrogen balance is most important in the calculation but due consideration should be given to the metabolic rate.

In the preoperative preparation of patients with malnutrition and hypoproteinemia. There is here the double nutritional disturbance resulting from (1) the indication for operation (gastrointestinal disease with either vomiting and/or diarrhea, carcinoma, dysenteries, hyperthyroidism, hepatic disease, and so on) and (2) the operation itself.

All grades of malnutrition will be present but as a general rule it is well to add together the protein loss present, and to be anticipated in the post-operative period plus an added increment for good measure. If the time available for this preparation is limited, the most strenuous methods (blood, plasma, and/or albumin transfusion) should be employed and the amounts given should be increased.

In the postoperative period. For those patients whose operations are necessitated by conditions unassociated with protein deficiencies, no particu-

lar protein replacement should be done as these subjects accumulate and replace any lost protein as soon as they are back on a normal, or somewhat richer normal diet.

In all other patients, in accordance with the degree of the deficiency the length of time it has existed, the nature of the operation, and so on the deficiency should be calculated and replaced as in the preoperative preparation, of which the post operative therapy is only a continuation with some intensification of the program.

In industrial practice. Physicians should give adequate information to workers on the importance of a rich protein diet for the various reasons outlined in this communication. Emphasis should be placed upon this again and again in order to have this register adequately in the workers' minds. It might be well to distribute pamphlets containing all of this information with specific directions as to diet fractions, and so forth and how to secure and prepare diets with abundant and palatable protein. As a general rule if the usual protein quantity be doubled in an otherwise apparently healthy individual the diet will be protein rich enough for all practical purposes.

Information should also be distributed by lectures and pamphlets as to the relationship of deficient protein to undue fatigue and to latent or apparent liver parenchymal disease. The workers should be warned and encouraged to report to the company physicians if any of these symptoms appear so that the appropriate tests can be made and measures instituted for the correction of any protein deficiency. Diets should have the guidance of nitrogen balance studies. Under any such conditions, however, a diet as rich in protein as the patient can take, according to the directions herein after given for malnutrition and hepatic disease should be prescribed. Whenever indicated by study of the patient, the diets should be fortified with amino acids and in emergency conditions other methods of administration besides the oral should be freely employed.

In military front-line conditions. Soldiers have always been provided with portable and emergency extra rations in which carbohydrate was the main ingredient on the theory that carbohydrate was what the soldier needed most, and because of its quick utilization and effect. It appears from the newer knowledge that while carbohydrate is truly valuable, protein is much more valuable because of its increased and more prolonged effect and from the standpoint of guarding the individual against infection in wounds, increasing his healing abilities, giving a greater sense of well being and preventing or neutralizing fatigue.

Under such conditions it seems better to enrich the protein content of these rations to at least a 50 per cent increase. Under any battle conditions the protein content of the soldier's diet should be the richest which can be provided.

Methods and rules of administering protein therapy in pathological states in practice

1 Increase the dietary protein intake to between 150 and 180 gm per day. Usually the patient will not or cannot take more by mouth.

2 Use gastric intubation if possible. This may add as much as 50 per cent to the dietary intake. However if too much is given, the subjects become distended develop diarrhea, and much protein is lost.

If because of a digestive or other disability the amount of protein taken is not sufficient, the discrepancy should be made good by adding a sufficient quantity of amino acids dissolved or mixed with the food. This is easily done in feeding by mouth and even more easily accomplished by intubation.

3 Give protein by the intravenous route.

a Transudate (pleural or ascitic) fluid. The protein concentration will vary between 2 and 4 per cent. Usually great bulk must be given to make up for the lack of concentration. It is, perhaps, best to give a moderate quantity at the first administration (250 cc.) as a test for any possible untoward reaction. If any reaction takes place, it might be advisable to use fluid from another donor source. Thereafter if enough transudate fluid is available, one can give as much as 500 cc. every other day in moderately severe deficiency conditions, and in exceptional cases this amount may be given every day. More than the usual care is necessary to ensure sterility otherwise reactions are more common than in other transfusions especially if any source of infection is present.

A coagulum frequently forms in the pleural transudate. This should be filtered out through eight or ten thicknesses of gauze, and at the same time the fluid will be cleared of any cellular content. The protein lost in the coagulum is very small—frequently only $\frac{1}{4}$ per cent or less, of the total contained in the transudate. The transudate fluid should be kept warm (not over 56 degrees) during the transfusion.

The use of transudate fluid will find its best place in the replacement therapy of nutritional edema.

Transudate fluid should be an important source of protein for replacement in chronic protein deficiencies. Possibly when it is furnished commercially methods of collection, processing and preparation will be better than those used at

present, and reactions will be eliminated or much lessened.

b. Plasma. One may increase the protein concentration by adding dried plasma from one bottle to freshly dissolved plasma in the usual concentration. As high as a 10-to-12 per cent concentration may be obtained in this way.

Plasma is most valuable in the immediate period after severe and extensive burns. As much as from 4,000 to 5,000 cc. must be given each twenty four hours in order to replace the enormous protein loss through the burned area.

c. Whole blood. This furnishes more protein than transudate fluid or plasma, but the evidence is not sufficient that blood can be used as a source for the protein needs of the organism. 1,000 cc. of whole blood equal 35 gm. of plasma protein and 70 gm. of globin and erythrocyte protein.

d. Amino acids. The solution should be non-toxic, nonantigenic, and biologically adequate. In intravenous use the limiting factor is the amount of vascular sclerosis which might follow. This can be avoided by use of the subcutaneous or intrasternal routes.

A good formula for the parenteral solution is the following

Amino-acids	30 gm.
Solu-B	1 ampoule
Glucose (5 per cent) in normal saline solution	1,000 cc.

A safe rate of speed for the administration is 30 drops to the minute.

Solu B is a vitamin preparation of special potency for intramuscular or intravenous use. Each ampoule contains the following

Thiamine hydrochloride	10 mgm.
Riboflavin	10 mgm.
Pyridoxine hydrochloride	5 mgm.
Calcium pantothenate	50 mgm.
Nicotinamide	250 mgm.

Only one ampoule is given in twenty-four hours.

e. Albumin solution (25 per cent). In chronic hypoproteinemias and protein deficiencies, these suggestions should be followed in the order given in accordance with the needs of the given situation. In cases due to injury (burns, and so on), or in those in which surgery is contemplated or has already been done, it will be found necessary to reverse the order. I. e., begin with parenteral methods and proceed as soon as convenient or practical to a combination of parenteral and enteral methods, and, finally as soon as the patient's digestive powers have returned to the necessary degree, use enteral methods alone.

In chronic hypoproteinemias of long standing, not associated with any form of surgery it is possible, as Elman (6, 7) has done, to evolve a rough equation according to which the protein needs (protein deficit) can be calculated. However this has two disadvantages (1) under the best conditions, the equation is not as accurate as it apparently seems to be, and for safety's sake the calculated amounts should be increased to make up the margin of error; and (2) the underlying disturbance does not respond to correction on any time schedule and continues for an undeterminable period until recovery takes place, therefore it is best not to set any time limit in which the correction is to be made. In some cases, the underlying condition is irreversible and protein replacement therapy must continue indefinitely.

It is better to calculate the daily requirement as follows

$(MED + DL + NUP) \times 2$ in which
 MED = minimum endogenous daily protein need, usually 25 gm.
 DL = daily loss of protein determined from N balance
 NUP = part of diet protein which is not utilized (estimated)

The factor 2 is arbitrarily chosen to make good any error and to furnish the additional protein from which the contemplated gain is to be made in the correction of the protein deficiency. This calculation can be made quite easily and such amounts permit the subject to regain the normal protein content with a speed that the body can tolerate. In good subjects, the arbitrary factor 2 can be raised to 3 and even 4. The presence of any hepatic parenchymal disease of any grade makes for difficulty because of the inherent inability of the diseased liver to metabolize the administered protein. It is important never to overtax the capabilities of the subject to absorb the given amounts as otherwise the endeavor will be fruitless. Ultimately the amount of total protein needed to replace and make good any deficiency is relatively and actually very large.

The observations of Hoffman, Meyer and Kozoll (Preliminary Studies in Amino-Acid Therapy. *Proc. Central Soc. Clin. Res.*, 1944 17. Seventeenth Annual Meeting, Chicago, Illinois, November 3 and 4, 1944) indicate that after the parenteral administration of amino acids the curve indicates that the amino acids leave the blood almost as fast as they enter and since little of the amino acids can be accounted for in the urine, they must have been taken up by the tis-

ses. Retention in the plasma after oral administration is only slightly longer.

Reliance on the plasma protein level as a guide for the efficacy of the administered amino-acid supply is fallacious. Clinical hypoproteinemia represents a far more serious deficiency of tissue protein than that indicated in the plasma protein level. Hypoproteinemia means a loss of tissue protein at least 30 times as great as the plasma protein deficiency. Such deficiencies cannot be alleviated by isolated or haphazard injections of plasma. From Elman's calculation, an average of about 375 gm. of protein is required each day for ten days to raise a serum-protein level from 5 to 7 gm. per cent. Should this regimen give the desired rise in plasma-protein level it does not necessarily mean that an equally successful replacement has taken place in the reserves and tissue proteins. Similar conclusions seem in order for other forms of replacement protein therapy.

In long-standing cases of protein deficiency in which the deficiency is great and the daily nitrogen excretion excessively high, parenteral amino-acid therapy is usually insufficient to remedy the deficiency and plasma and blood transfusion are not feasible because of expense. All parenteral replacement therapy is indicated in acute conditions when the deficiency has occurred suddenly or comparatively quickly. In the long-standing cases most brilliant results appear to be achieved with a long-continued very high protein diet fortified with large oral doses of amino acids, and interspersed, as the need arises, with blood plasma and/or ascitic or pleural fluid transfusions.

The object to be accomplished in chronic protein deficiencies is the building-up of tissue and reserve protein to something like the normal amount. If the available observations are correct it seems that much larger nitrogen balances than those previously thought necessary must be established and retained for a much longer period of time, and the extent of the latter is not predictable but a matter of continued observation. The best guide for the success of the replacement therapy is not the proteinemia level but the gain in total body weight.

THE CLINICAL RESPONSE OF HYPOPROTEINEMIC STATES TO REPLACEMENT THERAPY

The response to replacement therapy of any hypoproteinemia will depend to a large extent upon the mechanism of its production. The severe liver damage of the hepatic type renders hypoproteinemia least responsive to treatment. The posthepatic type of hypoproteinemia associated with burns usually responds rapidly to efficient

early treatment. The response of the hepatic type depends largely upon the length of time the hypoproteinemia has existed and the amount of irreversible damage that has occurred. The prehepatic type responds to treatment in proportion to the nature of the cause.

The favorable effect of efficient treatment in clinical states of hypoproteinemia depends upon (a) the ability to remove the underlying cause (b) the ability to rectify any disturbance of liver function (c) the relative shortness of time for which these two primary factors have existed and (d) the relative lack of pathological anatomical changes such as edema and tissue protein defects. Good and favorable results of efficient treatment cannot be expected when these factors cannot be eliminated or when any degree of infection is present and cannot be controlled.

THE EFFECT OF THERAPY

Adequate knowledge has greatly enlarged the sphere of replacement and enrichment protein therapy as a protective effect (1) for preventing any impairment of the normal functions of the liver (2) for preventing the deposition of fat in the liver cell (3) for a powerful lipotropic activity when abnormal amounts of fat have previously been so deposited, (4) for lessening the susceptibility and increasing the resistance to toxic and chemical injuries, to infection (antibody formation) and to other forms of disease (5) in the treatment of some medical conditions (such as the cirrhoses) in which protein deficiency is both a potential cause of the disease and an important consequence (6) in the treatment of conditions such as burns in which there is a sudden depletion of protein stores (7) in the facilitation of reparative efforts after chemical and/or toxic injury of the liver parenchyma (8) in the better general preparation of patients for any contemplated operation (9) for the prevention of potential specific dangers, such as postoperative hemorrhage (10) in lessening the injurious effect upon the liver cell of drugs of the sulfanilamide group (11) in lessening the risk of general and spinal anesthesia and (12) in enhancing the efficiency of healing in operative and other types of wounds.

Several points have resulted from this study which seem to have a profound clinical importance. In view of the present tendency toward dieting, one should appreciate the fact that this may produce a state of undernutrition protein deficiency and hypoproteinemia, the symptoms of which perhaps little understood until now include (1) loss of weight and strength, (2) loss of stamina or 'pep' (3) various degrees of chronic

fatigue, and (4) a much lessened resistance to disease. In many cases, this latency predisposes to more profound changes, especially in the functions of the liver. And the prevalence of such latent conditions is very little understood at its true clinical importance among the profession.

It seems to be true that fat people are not necessarily "well nourished." In this type of person usually the available protein is relatively overshadowed by the fat content. A surgeon appreciates this because of his experience that such individuals are not good subjects for surgery.

The impression is growing that, clinically, an enriched protein diet is not only advantageous but also very necessary for anyone about to undergo the abnormal physical strain of surgery with its attendant risk of infection, trauma, and so on, and for the prevention of any danger of postoperative hemorrhage. In this regard, the previous belief that a preponderating rich carbohydrate diet was necessary has suffered.

All of these facts have special significance in military and battle conditions and in the convalescing period of any wounded or otherwise injured person. All of these facts have very special importance in industrial practice, as heretofore indicated. In the latter, employers and their medical advisers are only just beginning to appreciate the important relation of an adequately rich protein content of the food of the worker to his productive capacity as the former eliminates fatigue and corrects any latent disease, and thus increases the earnings of the worker and the profit of the employer.

Similarly, it seems that if at any time, there arises the necessity for the administration of any drug which might have a deleterious and/or toxic action upon the liver, one should supply a very rich protein diet, which would have the tendency to forestall such injury.

The relative importance of the protein fractions is only now becoming sufficiently known and understood. The proteins guard the body's ability to replace its losses through ordinary wear and tear as well as through disease and operative procedures, and they increase the readiness of wounds to heal. Dietary protein protects the organism from infection by supplying the material from which antibodies may be fabricated as the consequence of appropriate antigenic stimuli. By virtue of their lipotropic power they help to restrain any tendency to store abnormal amounts of fat in the various organs, notably in the liver. They furnish the factors which control hemorrhage, and an abundant, rich protein supply gives a sense of well-being and vigor and does away with fatigue.

UNKNOWN FACTORS

There seems to be a great necessity for the study of certain hitherto elusive factors which seemingly have a profound effect. Not always do the available methods of therapy and protein replacement bring about the desired results to our clinical satisfaction. For instance, it frequently happens that either plasma or whole-blood transfusions are given and not much change is apparent then a transfusion is given from another donor, and the result seems almost miraculous. It must be, therefore, that certain factors which had not been present previously become available and are provided through the agency of the new donor. Not infrequently these effects are seen clinically.

MEMORANDA ON COMMERCIALLY AVAILABLE PROTEIN HYDROLYSATE PRODUCTS

At this writing only three protein hydrolysate preparations are available on the open market. Each of these is listed below with a short statement as to its method of preparation and its use, as well as with some indications of its advantages and disadvantages.

Aminoids. This is the only product of its kind accepted by the Council on Foods and Nutrition of the American Medical Association. It represents the enzymatic digest of a multiple source, yeast, beef, wheat and milk, to which carbohydrate are added. It is designed exclusively for direct introduction to the gastrointestinal tract either orally or orojugally. Aminoids contain a mixture of amino acids and peptides which is readily absorbed and assimilated. The added carbohydrates exert a favorable protein-sparing action. The product is marketed in the form of dry granules, is satisfactorily palatable, and, in addition, may be readily incorporated in a variety of vehicles, which favors prolonged acceptability by eliminating monotony. The biological adequacy of the product has been established by a number of animal tests as well as by the results of clinical work in human beings (Beling and Lee, *Arch. Surg.* 1941, 43, 735) and this product has been found satisfactory as an adjuvant nutrient whenever protein deficiencies were suspected or when there was an increased need for protein.

Amigen. This product is a pancreatic hydrolysate of casein. Digested close to the limit of pancreatic proteolysis, it is well suited for parenteral use. Limitations to its use are the need for a comparatively slow rate of administration in order to avoid undesirable reactions. The product has high biological adequacy as attested to by many animal experiments. It is available in flasks in dextrose solution ready for parenteral intro-

duction and is also marketed in the form of a dry powder. The manufacturers also recommend its use orally. There is some question as to its palatability (Peters, *Federation Proc.* 3 1938), but the manufacturers say "if an individual makes up his mind to take the solution and will drink a concentrated solution rapidly and follow promptly with a chaser it can be taken with a minimum of unpleasantness. Orojejunal use of the preparation has been accomplished successfully.

Paroxamine Until recently this product was marketed under the name Amino Acids. This hydrolysate is available in bottles containing 100 cc. of a 15 per cent solution of amino-acid materials derived from the acid hydrolysis of casein. The hydrolytic products are fortified by the addition of a reasonable quantity of tryptophane. The biological adequacy of the original product was questioned by Madden and his associates. Since then the manufacturers have devised a new method for the preparation of stable di-tryptophane and this is contained in the new product which is now being distributed for use. The product has been used with success in many clinical conditions. Its parenteral administration must be done cautiously as too rapid a rate will give severe reactions which are attributed to hyperaminoacidemia. This hydrolysate has been recommended also for oral administration but again the question of palatability enters to a very serious extent. Further it is uneconomic to purchase material especially processed to be administered parenterally and then use it orally. This, of course, puts the burden of unnecessary expense upon the patient.

In addition to the foregoing much experimental work is going on with various hydrolysates and other nitrogen-containing preparations. Highly promising results have been obtained by the use of mixtures of crystalline amino acids which seem to be very efficiently utilized and free of many of the adverse effects noted for parenteral hydroly-

sates in the foregoing. The current scarcity of such materials, however, makes it unlikely that they will be in general use for clinical purposes for some time to come.

Extensive investigative work along lines designed to produce satisfactory protein hydrolysates for oral or parenteral use is being undertaken by a number of pharmaceutical houses.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Muntarhorn S.: Cavernous-Sinus Thrombosis Treated with Heparin and Sulfathiazole. *Lancet*, Lond., 1945, 245, 10.

A case of cavernous-sinus thrombosis or bilateral orbital cellulitis was treated with 42 gm. of sulfathiazole given orally at the rate of 1 gm. every four hours and 1 gm. of soluble sulfapyridine given intramuscularly for three days. Heparin was given in an intravenous glucose-saline drip hourly at first and continuously from the second day onward in all, 120,000 units were given over five days. The clotting time during this period was 16 in thirty minutes. The patient made an uneventful recovery.

ADRIAN VERBURGHEM, M.D.

EYE

Wright, R. E., and Duncan, H. A. G.: The Giant Magnet in Ophthalmic Battle Casualties. *Brit. M. J.*, 1944, 2, 652.

The authors report the case of a land mine casualty from Normandy who was admitted to No. 4 Canadian General Hospital. One of the wounds was a penetrating injury of the left eyeball. A small foreign body was found to be impacted in the retina about 3 disc diameters down and in front of the disc. The entrance wound was minute near the limbus toward 9 o'clock. There was hemorrhage of the retina near the track of the missile but the lens and vitreous were clear. The vision was 20/20. A roentgenograph showed a single minute opacity corresponding in position to the visible foreign body. Operation was performed under novocain infiltration on July 15, 1944, the same day the injury was received. Good rotation was ensured by dividing the mesial rectus. A 3-mm. incision was made in the sclera through a linear diathermy coagulation between points of fine silk suture. The incision was seen to be about 1 mm. from the foreign body which was partially hidden by coagulum. Six short applications of the giant magnet with the tip of a beak shaped terminal on the wound produced no movement. It was considered inadvisable at this time to extract the particle with forceps. The patient was retained for further consideration. The next day the authors were dealing with a minute metallic foreign body in the vitreous of a German prisoner of war by the posterior route and observed a slight rocking of the foreign body at the end of about the tenth short application as the current went off and on. Thereafter the particle made larger excursions from the center of the vitreous toward the wound and was delivered through the choroid (which had not been

incised) at the thirty-fifth application. The immediate postoperative progress in this case was uneventful; the eye remained quiet, the vitreous clear and the vision 6/6. This experience encouraged the authors to continue with the magnet extraction in the case tried the day before. On July 28 the sclera was exposed down to the previous wound and the curved terminal placed against it toward the side away from the foreign body. The magnet was then used in short bursts of about four seconds (on a few occasions as long as fifteen seconds) for 75 applications. The current was flowing probably for not more than a total of ten minutes. During this time the foreign body was observed to rock in its bed of coagulum, gradually come out of it and lie across the wound. The magnet was then too hot to manipulate and it was considered that its insulation was in danger. The patient was returned to bed. On August 2, under continuous pentothal anesthesia, the mesial sclera was freely exposed and the internal rectus was divided again to give free access. The sclera suture was removed from the original wound on which the beak-shaped terminal was placed. The wound elevated slightly at the first magnet application and the particle, smaller in size than the head of a 35 inch pin came out at the sixth trial without any hemorrhage or discharge of vitreous. The post-operative course was uneventful, the vitreous remained clear and vision was good (6/6 with lens).

It has long been known that intermittent applications repeated at a number of sittings will succeed in moving a feebly magnetic particle. It may not be generally realized that a small magnetic foreign body or larger feebly magnetic particle may behave as a nonmetallic foreign body for a considerable number of magnet applications and be labelled as such. Moreover with such particles the magnet test of pain production in a cocaineized eye is useless.

There are further lessons to be learned from this case and other recent cases observed:

1. The posterior route is ordinarily best for the removal of foreign bodies in the posterior segment.

2. The shortest route to the exterior is probably always best provided it does not drag the particle over or through an intraocular part or structure of relatively greater importance than that in which it is lodged.

3. A beak-shaped magnet terminal is almost essential for work well behind the equator; a blunt core shaped terminal is sometimes dangerous, especially with highly magnetic large bodies, unless they are situated in the anterior segment since the field is too diffuse to direct the delivery accurately.

4. It is possible that the removal of small metallic intraocular foreign bodies of feeble magnetism (as

in the case of iron compounds) is determined by the patience and perseverance of the operator and the patient, and the life of the magnet and rectifier more often than we have thought heretofore.

5. It is perhaps stating the obvious to say that examination of intraocular foreign bodies lodged superficially in the skin of the face or body or in the conjunctiva, is desirable in order to determine their composition and magnetism.

6. To those accustomed to the localization of foreign bodies in civil hospitals in peacetime the slower and less accurate methods necessitated by war conditions constitute a great handicap.

7. The fact that frequent applications of the giant magnet increase the magnetism of feebly magnetic alloys should influence the technique.

8. The application of a surface diathermy terminal to the sclera in the neighborhood of a metallic intraocular foreign body is likely to produce an uncontrollable reaction emanating from the foreign body. For this reason and because of the greater difficulty of withdrawing a magnetic particle from a bed of coagulum, it is probably better technique to apply diathermy to the neighborhood of the scleral wound after the foreign body is removed.

9. If prolonged applications of the Army portable giant magnet are required as in the case described it is almost essential to place it on an adjustable stand with a tilting top beside the operating table.

CHARLES BARON M.D.

Dunnington J. H., and Sellmann, L. von: Penicillin Therapy in Ophthalmology. *Arch. Ophth.* Chic., 1944, 33: 353

Ten clinical cases of eye conditions treated with penicillin are reported, and the difficulty in evaluating the role of penicillin in determining their subsequent course is discussed. The effectiveness of treatment in infections of the lid border and conjunctiva with pyogenic cocci and gonococci seems well established. There are as yet too few cases to permit an adequate opinion regarding many of the deeper infections of the globe. Some of the clinical cases were given simultaneous sulfonamide therapy and the combination may prove to be more effective.

Experimental work was carried out on rabbits whose lenses were inoculated with the staphylococcus aureus. Iontophoretic application of penicillin, after an interval of six hours, checked the infection in none of the cases. When penicillin was injected into the lens six hours after inoculation the infection was checked in all of the cases but when twenty-four hours elapsed it was checked in only 2 of 10 cases.

Further experimental work was done by the direct injection of penicillin into the vitreous. Staphylococcus infection in the vitreous was arrested with a single injection of penicillin when administered within twelve hours after inoculation. If a period of twenty-four hours elapsed between the inoculation and the treatment the infection was not successful.

The injection of penicillin into the anterior chamber of the rabbit caused only a transient inflamma-

tory reaction of mild degree lasting from one to three days, and the authors conclude that this may be an effective method of administering penicillin in the human eye when transcorneal introduction by iontophoresis cannot be used.

EAR

Patterson, W. H., and Smith, G. S.: Latent Mastoiditis in Infancy. *Brit. M. J.*, 1944, 2: 659.

In a series of 120 autopsies in infants and young children, pus was found in the mastoid cavities of 71. Although the highest incidence was observed among patients with a clinical history of diarrhea and vomiting, pus was found almost as often in patients with a wide variety of conditions. Clinical postmortem, and bacteriological findings suggest that so-called "latent mastoiditis" is not an etiological factor in the diarrhea-and-vomiting syndrome.

CHARLES BARON, M.D.

NOSE AND SINUSES

Whalen E. J.: Sulfonamide Compounds in the Treatment of Infections of the Nasal Sinuses. *Arch. Otol. Chic.*, 1944, 40: 481

The sulfonamide compounds Whalen declares, are not effective as bacteriostatic agents when used on the unbroken surface of the skin or of the mucous membrane. It is for this reason that it seems illogical to use solutions or suspensions of these drugs for local application to the unbroken mucous membrane of the nose with the expectation that disease-producing organisms in the soft tissues will be affected or controlled. The oral or the intravenous administration of these new chemical agents is the only means by which they can be brought in contact with the disease-producing organisms that are lodged in the lining membranes of the nasal sinuses. They must be used early in the acute infection before the infected area is closed off by thrombosed vessels.

Rhinologists must review their pathology, revise their surgery and integrate their knowledge of the new chemotherapeutic agents. With proper timing of indicated surgical intervention, co-ordinated with systemic use of the new drugs and the application of selected bacteriostatic substances to the field of surgical operation sinus infections of many types can be brought quickly under control.

The local use of sulfadiazine in the concentration of 2.5 per cent in aerosol was found to be without effect in controlling the progress of nasal sinus disease either the acute or the chronic type. Wetting agents were used as vehicles to carry the sulfonamide compounds in the belief that their detergent characteristics would aid in the penetration of the ostium of the sinuses. The experiment was a complete failure. An attempt at forcing the sulfonamide compounds into these cavities by the displacement method of creating a partial vacuum in the sinuses was without success since contrast mediums and other

solutions were found only in small quantities and in a limited number of the sinuses so treated.

The only successful mode of chemotherapy for disease of the nasal sinuses was found to be that of giving full doses of the sulfonamide compounds by mouth. This treatment must be carried on under observation in a hospital where bacteriological studies can be made, the blood level controlled, and the blood picture and renal functions frequently observed. With this treatment a large number of sinus infections both of an acute and a chronic nature can be brought under control.

NOAH D. FAIRCLOTT, M.D.

NECK

Figt. F. A., Rowland, W. D., and New, G. B.: Cyst adenoma of the Larynx; Report of 4 Cases. *Arch. Otolar. Chic.*, 944, 40-445.

A cystadenoma may be defined as an adenoma that has undergone cystic degeneration. Adenomas and cystadenomas may originate in any part of the larynx, except possibly the free edges of the vocal cords since these are covered with squamous epithelium and are practically devoid of mucous glands. The most frequent sites of origin are the ventricles, ventricular bands, epiglottis, and subglottic region. The tumor may range from a few millimeters to several centimeters in diameter. The cystic character of the growth may or may not be evident on clinical examination. A single large cyst may be present or

the tumor may be multilocular. Commonly the growth is covered with normal appearing mucous membrane, but in some cases the mucous membrane is thickened and injected. The enlargement may be slightly yellowish in areas or throughout its extent because of the fact that the cystic contents show through.

The treatment of these tumors depends on their situation and size. Readily accessible lesions of limited extent can be removed by indirect or direct laryngoscopy but extensive growths may require laryngotomy. Indirect removal using a curved forceps and electrocoagulation is feasible but is gradually becoming a lost art in the treatment of benign laryngeal neoplasms generally. Direct laryngoscopy using either the laryngoscope or the suspension apparatus, is preferable in most instances. Suspension laryngoscopy usually is the treatment of choice for the removal of these tumors since it affords a wider field of vision than other methods and permits the surgeon to use both hands, which enables him to carry out limited dissection. If the tumor extends deeply in the region of the ventricle or into the ventricular band, or if it is growing beyond the larynx, thyrotomy probably will be necessary.

Unless the tumor is obviously benign and well localized and its limits are definitely evident on direct examination biopsy should be performed before treatment is instituted. The picture presented by a cystadenoma of the larynx may be closely simulated by a malignant tumor developing in the ventricle.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

German, W J Brody B. S. and Harvey S. C.
Compound Craniofacial Injuries. *Surgery*
1944, 16: 374.

A review of the treatment of compound craniofacial injuries is made and a comparison of earlier methods of treatment and results with those of the present day is made. A series of 64 cases of compound craniofacial injuries was treated at the New Haven Hospital, New Haven, Connecticut. The early treatment of such wounds is emphasized as important in avoiding infection and the complications which result therefrom.

The general policy of treatment as outlined included (1) immediate treatment of shock, if present (2) inspection, not palpation of the wound (3) roentgenography to determine the extent of fracture especially the depression or the sinus involvement and (4) operation within six hours in all patients surviving the preparatory period. Local anesthesia was the anesthetic of choice.

The surgical procedure followed in this series, and recommended by the authors, included (1) thorough debridement of the scalp cranial wound and devitalized brain tissue (2) removal of undriven bone fragments and foreign bodies (3) closure of the dura with silk, if possible (4) closure of the scalp in two layers with silk and (5) drainage of the frontal sinus, and of most wounds, for culture. The bone removal was usually en bloc for the comminuted and depressed fractures unless the frontal or sagittal sinuses were found to be involved in which case fragments were removed.

The mortality rate in this series showed a marked increase with the advancing age of the patients. All patients in the seventh and eighth decades succumbed.

Of 51 patients who lived more than six days 20 per cent had postoperative infection. The total mortality in the series of 64 patients was 26.5 per cent.

HOWARD A. BROWN M.D.

Lanigan J P: Traumatic Subdural Effusion in Children. *Lancet, Lond.* 1944, 2: 686.

Three cases of subdural effusion in children are reported. The patients gave a history of trauma which had been followed by signs of increased intracranial pressure and a localizing condition indicative of a gross lesion. At operation a quantity of clear fluid was encountered beneath the dura, and upon release the brain resumed pulsation and gradually began to come up to the dural level. Improvement was very prompt from the standpoint of consciousness and decrease in the motor disturbances.

Operation consisted of exposure through a trephine opening, which was slightly enlarged for purposes of vision.

HOWARD A. BROWN M.D.

Meacham, W F Smith, E., and Pilcher C.:
Chemotherapy of Intracranial Infections; The
Treatment of Staphylococcal and Pneumococ-
cal Meningitis with Sulfathiazole and Sulfadiazine. *W or Med.*, Chic., 1944, 6: 378.

The authors have undertaken a series of studies on cranial infections, and the present article the fifth in the series, concerns the treatment of staphylococcal and pneumococcal meningitis with sulfathiazole and sulfadiazine. The report deals with the results obtained in 116 experiments in which the same types of meningitis were treated by oral administration of sulfathiazole and sulfadiazine, and in 36 experiments in which the intrathecal administration of a suspension of microcrystalline sulfadiazine was employed. Experiments were carried out in groups of 12, half of each group being treated and the other half being kept as untreated controls. The treatment was begun forty-eight hours prior to the external injection of the organisms. The treated animals were given 0.5 gm. of the drug orally every eight hours.

In the first experiments, the staphylococcal meningitis was treated by oral administration of sulfathiazole and there was no significant difference between the treated animals and the controls.

In the next group the meningitis was treated by the oral administration of sulfadiazine, and in this group the mortality was definitely lower. Three groups of 12 dogs were treated by the intracranial injection of a suspension of microcrystalline sulfadiazine. Following this, no convulsions were seen, but several animals had an extreme transitory opisthotonos immediately following the injection, and at necropsy a thick, pasty layer of the drug was found to extend far forward under the base of the brain.

With regard to pneumococcal meningitis, this was produced in 4 groups of 12 dogs and these were treated with sulfadiazine and sulfathiazole by mouth. Higher concentrations of sulfadiazine were found in the spinal fluid of these dogs than in those suffering from staphylococcal meningitis. In fact, the percentage of recovery from pneumococcal meningitis was proportional to the concentration of sulfadiazine in the cerebrospinal fluid.

From these studies it is apparent that, in conformance with previous observations, sulfadiazine was present in much higher concentration in the spinal fluid than sulfathiazole after oral administration. The staphylococcal meningitis produced in these experiments was not benefited by the oral use of sulfathiazole. On the other hand the oral administration of sulfadiazine was distinctly beneficial. Intrathecal injections of microcrystalline sulfadiazine were not considered beneficial in fact, they were believed to be harmful. A high concentration of sulfadiazine in the spinal fluid is essential for recovery from experimental pneumococcal meningitis.

ADRIAN VERBURGEN M.D.

Collis, J. L.: The Etiology of Cerebral Abscess as a Complication of Thoracic Disease. *J. Thorac. Surg.* 1944, 13: 445.

The incidence of brain abscesses following infection in the chest cavity and the route followed by the infection from the thorax to the brain have been somewhat prematurely taken for granted. This study was made for the purpose of clarifying views on these matters. Forty-six cases were collected from the Brompton Hospital, from the Birmingham United Hospital, and from an E. M. S. Chest Center in England, and the first 44 of these were used for compilation of statistical tables.

On reviewing the various tables submitted with regard to certain general factors involved in this type of brain abscess, some of these factors were regarded as of negative value for instance, the age, the side, and the site of the abscesses, the infecting organism, the number of abscesses found, and the side of the primary condition of the chest were so varied as to indicate nothing in particular. A second group of factors, however, were regarded as significant namely the preponderance of these abscesses in the male sex, the special clinical picture of this type of brain abscess, the similarity of the various aspects of the brain abscess—whether they were secondary to lung abscesses, empyema or bronchiectasis, the fact that the brain complications might follow disease in the lung or in the pleura, the fact that only chronic disease of the chest caused brain abscesses, the increased danger of this complication following surgical interference, and the absence of abscesses in other parts of the body associated with involvement of the brain.

The author was particularly interested in the manner in which the infection spread from the lung or pleura to the brain. It was first suggested that the connection was due to the passage of septic emboli from the lung to the brain. Although this has been a popular theory it has never withstood anatomical or experimental criticism. Although it might be true for the pulmonary circulation it certainly is not true for the pleural circulation which is involved in cases of empyema. Furthermore, very little cerebral manifestation of septic emboli has been observed clinically in the patient, and the classical picture of cerebral embolus has certainly not been fulfilled.

With the rejection of this theory the theory of parasagittal infection developed but there were many objections to it, particularly in cases of empyema, which are almost cured at the time that the brain abscess develops and the patient cannot at that time be said to be in a chronic septic state. The spirochetal theory was also examined, but as far as the author is concerned, he was not able to demonstrate spirochetes in the brain of any of his patients in the region of the abscess, but there are many artefacts which will give this false impression. Congenital heart disease such as patent foramen ovale was also investigated, but was not properly connected with this group of cases. It is apparent throughout that the place of empyema in the formation of brain abscess

is the stumbling block because the pleura has a different circulation from that of the lung.

In order to obtain information concerning other conditions in which substances pass from the lung to the brain, carcinoma was investigated. Whereas bronchial carcinoma most commonly causes metastases to the brain, carcinoma of the breast is in second place and the latter of course is a chest wall condition. It appears then that the only vessels which communicate between the lung, the chest wall, and the brain are the bronchial and intercostal veins, which drain into the azygos veins, the spinal veins also drain into the azygos system. These veins are valveless and gravity plays an important part in their flow.

Experiments were continued in which opaque materials were injected into intercostal veins, and it was surprising to find the ease with which the opaque material reached the brain via the inside of the spinal canal. It was attempted to reproduce the disease in cats, but, unfortunately this was unsuccessful. Experiments of this nature will have to wait until monkeys are available.

In view of this discussion and experimental work, considerable evidence was produced in favor of the fact that infected material is carried from the chest to the brain via the spinal veins.

ADRIAN V. LUBCHENCO, M.D.

Harris, W.: Paroxysmal and Postural Headaches from Intraventricular Cysts and Tumors. *Lancet*, Lond., 1944, 247: 654.

The author points out that cysts of the third and lateral ventricles often produce no physical sign, but may present the so-called classical triad of periodic headaches, vomiting and papilloedema. Such a syndrome would lead one to suspect the possibility of periodic obstruction of the ventricular system. Three cases of this type have been reported.

HOWARD A. BROWN, M.D.

Hammes, E. M., Jr.: The Reaction of the Meninges to Blood. *A. A. New Psychiat.* Chic., 1944, 311: 505.

Autogenous blood in the subarachnoid space of human patients is not well tolerated by the leptomeninges.

The meningeal reaction to blood is evident within two hours of the hemorrhage and begins as an outpouring of polymorphonuclear leucocytes, followed by the appearance of lymphocytes and large mononuclear phagocytes derived from the mesothelial lining cells of the arachnoid.

This cellular reaction is transient and persists only as long as blood, or products of breakdown of blood, are demonstrable in the subarachnoid space.

Permanent effects occur in the form of patchy fibrosis of the pia-arachnoid, with obliteration of the subarachnoid space. This can be demonstrated only after the blood has been present ten days or longer.

From this study, no conclusion can be drawn as to the effect on this meningeal reaction of drainage

d bloody cerebrospinal fluid by repeated lumbar puncture.

Rupture of an intracranial aneurysm is capable of producing sudden death. The patients rarely if ever have an associated intracerebral hemorrhage although intracerebral bleeding is a very common finding among those who survive the immediate result only to succumb hours or days later.

Intraventricular hemorrhage sufficient to produce dotted blood in the ventricles will not occur following rupture of an intracranial aneurysm unless there is an associated intracerebral hemorrhage.

SYMPATHETIC NERVES

Smithwick, R. H.: The Surgical Treatment of Hypertension. *N. York State J. M.*, 1944, 44: 3093.

The author discusses some of the problems of choosing the proper cases for lumbodorsal splanchnicectomy. A review of the clinical investigations during the past eleven years is used as a basis for the choice of patients who may be suitable or unsuitable for surgical treatment of this type. The details of the operative procedure have been described elsewhere.

In nearly all of a series of 156 cases, there was a significant and persistent lowering of the diastolic blood pressure following operation. This was associated with favorable changes in the eyegrounds, electrocardiograms, and in cardiac and renal function.

The results have been variously divided into groups, according to the degree of drop in the diastolic pressure. The results in women have been significantly better than in men. The cases have been divided into three types, according to the degree of pulse pressure. Surgical results have been poorest in patients with the highest pulse pressure.

The report is based on 215 patients of whom 179 are living from one to five years following operation, and of whom all had had diastolic blood-pressure levels between 100 and 170 prior to operation. All patients had been subjected to a detailed study from the standpoint of their cardiac function, renal function, and vascular status as estimated by examination of the fundi. They had also been subjected to postural and cold blood-pressure tests. Their blood-pressure response to sedation should be studied.

The decision as to operative advisability was based upon the evaluation of all these studies. Certain contraindications to surgery have been outlined. (1) patients with congestive heart failure and impaired kidney function, with elevated nonprotein nitrogen, or a reduction in intravenous phenolsulfonphthalein (an output to below 15 per cent in the first fifteen minutes) (2) male patients with resting diastolic levels of 140 or more unless they have had a cerebral vascular accident and there is no evidence of actual impending cardiac failure or failure of kidney function (3) women patients with resting diastolic levels of over 140—the same rule applying

as to men except that in the male it is suggested that the phenolsulfonphthalein output must be 20 per cent or more during the first fifteen minutes, while in women, operation may be contemplated if the phenolsulfonphthalein output is as low as 10 per cent or more during the first fifteen minutes.

Other tentative suggestions are made with regard to patients in certain special groups in which a study of the surgical results has indicated a probably poor result.

HOWARD A. BROWN, M.D.

MISCELLANEOUS

Peterson, E. W. Kent, B. S. and Cons W. V.: Intracranial Pressure in the Human Subject at Altitude. *Arch. New Psychol.* Chic., 1944 52: 520.

The authors undertook to study the effects of altitude on the human intracranial pressure in a patient with a large cranial defect. The cranial defect measured 16 by 10 by 2.5 cm. and was perfectly healed and freely mobile under stresses of artificially increased pressure.

The degree of herniation of this defect was measured when the patient while breathing oxygen was taken to an altitude of 30,000 feet at the rate of 3,000 feet per minute in a decompression chamber. Readings were taken every 10,000 feet on a specially improvised apparatus. Readings were taken also at 25,000 feet after the subject's mask had been removed for two minutes and twenty seconds. There were no significant changes in the intracranial pressure either while the subject was breathing oxygen at an increased altitude or while he was in an acutely anoxic state (exposure of two minutes and twenty seconds at an altitude of 25,000 feet).

With a specially constructed plethysmograph carefully fitted to the cranial defect further observations on the intracranial pressure failed to reveal significant alterations when the subject was breathing oxygen at altitudes of as high as 25,000 feet and when acute anoxia of from sixty to seventy seconds duration was induced at this altitude. With the same plethysmograph technique of recording changes in intracranial pressure, again no significant alterations were recorded either on ascent or descent when the patient was taken to 15,000 feet and kept at this level without oxygen for twenty minutes. A further ascent to 20,000 feet, where the patient remained for ten minutes without oxygen, likewise failed to cause a significant change in the intracranial pressure as recorded on the plethysmograph.

Direct observations were made on the intracranial pressure by means of lumbar puncture. In intact skull was simulated in this patient by closing the cranial defect with a plaster cast. In ascent to 30,000 feet with the patient breathing oxygen did not cause any increase in the spinal fluid pressure. As has been observed by others, minute bubbles were noted to be rising in the manometer after an altitude of 20,000 feet had been reached. Removal of the oxygen mask for ten minutes at 20,000 feet caused an increase of

only 23 mm. of spinal-fluid pressure. This was noted toward the end of the exposure to anoxia and the administration of oxygen caused no change in this pressure.

It was concluded that all of these approaches to the determination of the intracranial pressure showed that no significant increase in the intracranial pressure of man occurred at high altitude and under conditions either of sudden or of more prolonged anoxia. This is contrary to the conclusions of other workers in the field and is of importance insofar as it indicates that head injury casualties may be safely evacuated by air. **HENRY A. SUMNER, M.D.**

Peterson, E. W. Bornstein M. B., and Jaepser H. H. L.: Cerebrospinal Fluid Pressure under Conditions Existing at High Altitudes: A Critical Review. *Arch. New. Psychiat., Chic.*, 944, 5 400.

This is a critical review of the literature based on available reports relating to this subject. High altitudes result in the following changes: reduced barometric pressure, reduced temperature, and reduced tension of oxygen. There is no change in the percentage composition of the atmospheric gases.

From their review the authors conclude that reduced atmospheric pressure has very little influence on the intracranial pressure itself, however expansion of gas in the bowel at reduced pressure may increase the intracranial pressure secondarily to a rise in venous pressure. Cerebral edema may occur and cause increased intracranial pressure because of anoxia. It has been found that the arterial blood increases because of the anoxia of high altitude and this may be a further factor in increased intracranial pressure in the initial stages. It has been believed that the increase in intracranial pressure as analyzed by experts in the field, was not of sufficient magnitude to be of clinical significance.

The conclusion reached in this highly critical study is that significant increase of intracranial pressure will not occur in the sick or wounded during transportation by air provided anoxia is not permitted to occur. **ANDREW VANDERBOOMER, M.D.**

Peacher W. G., and Robertson, R. C. L.: Neurological Complications Following the Use of Continuous Caudal Anesthesia. *Arch. New. Psychiat., Chic.*, 944, 52 531.

Two cases of infection complicating the use of continuous caudal analgesia, which resulted in neurological changes, are reported.

The first case was one of immediate bilateral sciatica following forty-eight hours of continuous caudal analgesia. Objectively there was a sacral anesthesia with hyposthesia as high as the second

lumbar segment on the right, and as high as the fourth lumbar segment on the left. The cause of this proved to be a localized infection in or about the caudal subarachnoid sac. Culture of fluid aspirated from the caudal canal yielded the hemolytic streptococcus and the staphylococcus albus. Frank pus was obtained on lumbar puncture through the fourth lumbar interspace, a culture of which gave pure staphylococcus albus hemolyticus. No spinal fluid was obtained with this procedure and it could not be determined whether the pus was intra or extradural. Sulfathiazole (6 gm. daily for two weeks) was given, and the patient improved rapidly. She was asymptomatic and neurologically negative on discharge twenty four days postpartum and also on follow-up examination made one and one half years later.

The second patient had a normal delivery with sixteen and one-half hours of continuous caudal analgesia. Her postpartum course was normal until the ninth day after delivery when she complained of low back pain with bilateral sciatic radiation. There was questionable sensory impairment below the third lumbar segment, and bilateral Kernig and Brudzinski signs were present. There was a daily temperature elevation of 103 degrees. Remission occurred with the use of sulfadiazine, but six weeks postpartum the patient was readmitted to the hospital with a recurrence of symptoms. At this time there were hyperactive reflexes and bilateral Babinski signs, as well as signs of meningeal irritation. The temperature was elevated daily to from 100 to 101 F, and there was a leucocytosis of 14,800. Multiple lumbar punctures indicated the presence of a partial subarachnoid block between the second and the fifth lumbar interspaces, and pantopaque myelography gave the picture of a diffuse lumbar arachnoiditis. Laminectomy was performed and the arachnoiditis confirmed the roots of the cauda equina were separated and the dura was left open after a section of tantalum foil had been placed over the roots.

Operation relieved the sensory changes, but sphincter function did not return and lumbosacral pain persisted, as did motor impairment of the lower limbs.

Postoperative x-ray examination revealed an osteomyelitis of the first sacral to the second lumbar vertebral bodies, inclusive. No causative organisms could be identified.

From a review of the literature the authors conclude that the rate of infection in the production of complications following caudal anesthesia is second only to the introduction of the analgesic agent into the subarachnoid space. **HENRY A. SUMNER, M.D.**

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Smithy H. G.: Mixed Malignancy of the Breast. *Surgery* 1944, 16: 854.

The simultaneous occurrence of two different malignant processes at points of origin quite distinct and separate from each other is a well established entity. Much less common than these anatomically unrelated tumors is the presence of two different types of neoplastic tissue growing within the same organ.

Mixed malignancy of the breast can be divided into two categories: (1) the simultaneous presence of two distinct varieties of malignant tumors growing side by side but having no structural intermingling of their elements, and (2) a combination growth of two different malignant tissues, the component parts of which are intimately blended with one another into a single tumor. The first type may be regarded as a coincidental occurrence of two independent neoplasms in the same organ but the second type of mixed tumor of the breast can hardly be considered as an accidental coexistence of different neoplastic lesions. It appears likely that these tumors either arise from a single cell or one element occurs first and subsequently stimulates proliferation of the other.

Experimental observations lend support to the possibility that a malignant lesion of epiblastic origin can stimulate adjacent mesoblastic elements to proliferate, and vice versa. Widely divergent opinions prevail among pathologists concerning the possibility that combination growths can originate from a single cell, and no positive expression can be made at this time.

The authors report in detail an unusual case of mixed sarcoma and adenocarcinoma in a ten year old negro girl. The case is believed to be the first of its kind recorded in a child.

Regarding classification of the tumor it is desirable to avoid such terms as carcinosarcomatodes, carcinosarcoma, and sarcomacarcinoma, which have been employed to indicate the relative time of appearance of the different malignant components of a dual tumor as well as the preponderance of one element over the other. Actually the neoplasm described consisted of two well defined individual malignant tissues. Therefore for the purpose of clarity the authors suggest that it be called a mixed sarcoma and adenocarcinoma. The word mixed is an important qualifying descriptive factor designed to differentiate the tumor from a condition in which the sarcomatous and carcinomatous growths exist as separate, independent neoplasms in the same breast.

The development of a dual mammary neoplasm in a patient at ten years of age is extraordinary. Only 4 authentic cases of carcinoma of the breast have been reported as occurring before puberty.

While removal of the breast was considered necessary it was the impression of several examiners who saw the patient before operation that the lesion was benign, most probably mammary hyperplasia of an extreme degree. Accordingly a simple mastectomy was done. In general, mammary sarcomas rarely invade the axillary lymph nodes so that axillary dissection is generally considered illogical in the operative treatment of this lesion, removal of the breast and pectoral muscles being the procedure of choice. Discovery of the carcinomatous factor was made only after sections of the axillary lymphoid tissue were examined. The involved lymph node was excised only because of its proximity to the incision no attempt being made to dissect the axillary contents. Such being the case, the question arose as to the advisability of a second operation for removal of the pectoral muscles and the lymphoid structures of the axilla and the supraclavicular space, after discovery of the metastatic carcinoma. Probably such a radical procedure should have been carried out, but factors beyond control prevented it.

TRACHEA, LUNGS, AND PLEURA

Bird Acosta, I.: Pulmonary Suppuration Secondary to Cardiospasm. *Am J Roentg* 1944, 53: 481.

Pulmonary suppuration as a result of esophageal overflow has often been reported in the literature. Esophageal retention may be caused by carcinoma of the esophagus, strictures, foreign bodies, pulsation diverticulum, extrinsic esophageal pressure from adjacent tumors, and cardiospasm. Of all the causes of pulmonary suppuration following esophageal overflow cardiospasm, although a fairly common clinical entity is rarely considered.

The author reports 3 cases of pulmonary suppuration as a result of cardiospasm.

MAURICE D. SACHS, M.D.

Davidson L. R.: Hydatid Cysts of the Lung. *J Thorac Surg* 1944, 13: 471.

Hydatid cysts of the lung, while uncommon in this country (36 cases reported in the United States up to 1930) will unfortunately, be much more frequent in the returning soldiers. The geographical distribution of this condition is dependent on its incidence and distribution in reservoir hosts particularly sheep, cattle and pigs and cases are most frequently seen in sheep-raising countries such as Argentina, Uruguay, New Zealand, Australia, Italy, Syria, Greece, and Algiers.

The life cycle of the echinococcus begins in the infected intestine of the definitive host (dog, wolf or jackal) where the taenia are found. The untainted dog is infected by eating the organs of animals (intermediate or reservoir hosts, i.e. sheep or pigs) infected

Fig. 1. A, Hydatid cyst of lung; B, perivesicular pneumonia; C, double-domed arch (Cumbo's sign) and D camalote formation (From José Arce).

with fertile hydatid cysts. Man, while also an intermediate host, represents a dead end as far as the further development of the parasite is concerned as his flesh is never eaten.

The taenia echinococcus which resides by the thousands in the intestine of an infected dog is a four-segment tapeworm about 0.5 cm. long. From the terminal proglottid, innumerable ova are discharged which gain entrance into man through contaminated water or vegetables. The egg lodges in the human stomach where the embryo is freed when the coat is digested by the stomach acid. It then migrates through the gastric or duodenal wall, enters the venules, and is carried to the first barrier—the liver. There the embryo enters the larvated stage and, in growing, empties its center and forms a fluid-filled vesicle with an inner or germinal layer and an outer or laminated layer. From the former layer vacuolated masses of cells (brood capsules) protrude into the vesicle's cavity. These in turn give rise to scolices. Most of the capsules and scolices are pinched off the germinal layer and sink in the hydatid fluid to form "hydatid sand." As the vesicle grows it stimulates in the organ the formation of an adventitial layer of connective tissue which is separate from the vesicle but is part of the simple hydatid cyst. If the cyst were in a sheep and the infected organ were eaten by a dog, the ingested scolices would enter the small intestine to become new taenia.

Daughter cysts, usually sterile and without scolices or proliferating vesicles, are generally the result of mechanical, infectious or toxic influence. On

the other hand an infected cyst, if ruptured or aspirated, may discharge scolices into surrounding tissue and cause secondary cysts (secondary hydatidosis). Therefore when operating one must not permit any hydatid fluid or sand to contaminate the incisional or operative wound. For the same reason, one should never aspirate a cyst except at time of operation. If a primary cyst erodes the pulmonary vein, metastatic hydatidosis results.

The simple cyst fluid and membranes are sterile. If they enter a new phase and become complicated infection causes death of the cyst and the contents of the cyst are necrosed and fragmented and the vesicle virtually falls apart.

In the lung the vesicle is surrounded by adventitia and also a concentric layer of atelectasis. If on enlarging the cyst breaks into a bronchiole the perivesicle space communicates with the bronchiole. With coughing and straining, air may surround the vesicle and give a perivesicular pneumonia (B). If a larger opening occurs, air may enter the vesicle and produce Cumbo's sign (C) a double-domed arch. Finally when the membranes sink into the cavity and float upon the remaining fluid the camalote (D) formation is noted. These are considered pathognomonic roentgenographic findings for pulmonary hydatid cysts. (See Figure 1.)

For diagnosis one must recognize the difference between simple and complicated cysts, which may be either peripheral or central. The simple cyst is usually silent. Nonproductive cough is the first symptom. There usually is accompanying chest pain. Later there may be hemoptysis with a productive cough. When the cyst enlarges dyspnea may be manifest. Physical examination often suggests the diagnosis. In case of doubt the place where a patient lives is of utmost importance.

Laboratory methods are of some value in diagnosis but the procedures are not unequivocal. Eosinophilia is not present in dead or suppurating cysts. An eosinophilia (over 4 per cent) may not be present even in living cysts. The complement fixation test (Weinberg) and the more reliable intradermal test of Casanovi are not infallible. Certain diagnosis is made only when hooklets, scolices, or laminated membranes are found in the sputum. Characteristic x ray findings may establish the diagnosis even in complicated cases. Cysts are usually in the lower lobe and occur more frequently in males.

Medical treatment is of no value in echinococcus cysts surgery is the only satisfactory method of treatment. The presence or absence of pleural adhesions determines the type of surgical treatment, the essence of which is opening the chest, incising the cyst, and removing the membranes. The one-stage operation in the absence of adhesions is neither simple nor without definite risk, particularly that of pneumothorax. Central cysts are only attacked when they are draining poorly or when accompanied by fever and then only with caution.

The chest wall is opened over the cyst and the presence or absence of adhesions determined. These

may be shown preoperatively by a pneumothorax, but one may rupture peripheral cysts by pneumothorax. The cyst is entered and the membranes and contents are removed. Adhesions may be formed by packing the wound with gauze and reoperating two weeks later. A one-stage operation for an unadherent lung is accomplished by projecting the lung through the wound in the perietal pleura by using a tight fitting mask and increasing the positive pressure to 10 cm. of water at the appropriate time. The lung, if unadherent, may be sutured to the pleura outside of the cyst area to prevent pneumothorax.

The cyst may be treated in several ways. The wounds are draped meticulously before the cyst is opened. Fluid is withdrawn with an aspirating needle and a 2 per cent formalin is injected. The cyst wall is incised and the membranes are extracted from within the adventitia. The adventitia then may be completely sutured in a simple aseptic cyst, but in most cysts manipulation to establish drainage is the procedure of choice. Fluid is not always obtained in a complicated cyst.

It is not unusual to have a simple cyst leak and rupture into a bronchus or bronchiole. If this progresses, the fluid and the membranes may be extirpated and permit a spontaneous cure. If only the fluid is expelled the membranes remain and one may expect an infection or abscess formation.

The author then reports 4 cases. In the first a simple cyst was removed surgically with complete recovery. In the second case there was an intra thoracic hydatid cyst which may have arisen in the pedicle, body or lamina of the vertebra. The chief complaints were due to cord compression. The patient was operated on twice and is now working as a laborer without a brace. In the third case there was a complicated hydatid cyst of the left upper lobe. This was completely cured by operative drainage. In the last case there was a central hydatid with pneumothorax. Surgical drainage of the chest cavity only was attempted because of the central location. The patient died of a generalized peritonitis six months later without autopsy. ROBERT BICKLOW M.D.

Reinhoff, W. F., Jr.: Present Status of the Surgical Treatment of Primary Carcinoma of the Lung. *J. Am. M. Ass.*, 1944, 126 1123

Reinhoff reports a clinical analysis of and the results in 181 consecutive cases of primary carcinoma of the lung in which operation was performed over an eleven year period. Of this group 71 or 39 per cent, were operable. The sex incidence was 6 to 1 in favor of males the incidence of involvement of right and left sides was approximately the same. Sixty four of the patients were in the fourth to sixth decades, inclusive. The signs and symptoms that predominated in the order of their frequency were cough, hemoptysis, pain, weight loss, hyperpnea, pneumonitis, and fever. In general, there are no characteristic signs and symptoms of this disease—the lesion masquerades as many of the commoner disorders of the lung.

In this series of 181 cases the roentgenogram of the chest was positive in every instance. This diagnostic measure is the most important and the simplest method of examination. Second to x ray study is bronchoscopy.

In 70 per cent of the cases subjected to pneumonectomy there were metastases to the bronchial and tracheal nodes.

The microscopic appearance of these lung tumors made it possible to divide them into two large groups (1) the flat and (2) the squamous-cell carcinomas. The former gave a better prognosis.

The surgical treatment consists of total pneumonectomy. In this series 95 total pneumonectomies were performed the immediate mortality being 25 per cent. Thirty five per cent of the patients surviving are alive and well from one month to eleven years after the operation.

An otherwise fatal disease, primary carcinoma of the lung can be satisfactorily treated by surgical removal of the entire organ. Surgical measures short of total pneumonectomy are not efficacious. Post operative mortality and longevity are at least as good as, if not better than the postoperative results following the surgical treatment of carcinoma of other organs. J. M. MORA, M.D.

Kent, E. M., and Sager, W. W.: Current Practice in the Treatment of Thoracic Empyema. *Surg. Clin. N. America*, 1944, 24 1492.

The authors described their management of thoracic empyema at the United States Naval Hospital, Bethesda, Maryland. The choice between open and closed drainage is discussed. Open drainage is preferred when localization has occurred and when the pus is thick, such as in pneumococcal infections. When the pus is thinner especially with organisms such as the streptococcus or staphylococcus and when the empyema space is a large one they prefer closed drainage. By closed drainage is meant the insertion of an intercostal tube or catheter the distal end of which is placed under water. Later on it may be necessary to resect a rib and drain the cavity by open drainage. Tidal drainage may be used especially with the closed type of drainage when pus and fibrin obstruct the catheter.

It is estimated that 80 per cent of pneumonias are caused by the pneumococcus and the remainder by a variety of organisms. This holds true for empyema also but there is some variation from year to year and from place to place. Before the use of sulfonamides in the treatment of pneumonia the incidence of complicating empyema was from 5 to 6 per cent, but since the use of the sulfa drugs the incidence of complicating empyema is from 1 to 2 per cent. This decrease in the occurrence of empyema is found chiefly in the pneumococcal infections.

The fundamental principles are the same in both types of drainage. It must be carried out in a dependent position and maintained by close management. The tube must not become obstructed by fibrin or granulations; it should be shortened as the

cavity becomes obliterated rather than by a routine method for all cases. If the tube should slip out it must be replaced soon, because the opening in the chest wall contracts within a few hours and it may be impossible to reinsert another. The size of the cavity may be determined by filling it with sterile solution at intervals, or by x ray examinations. The tube should be left in place until the space holds less than 10 cc.

When an empyema has formed under sulfa treatment for the primary lung infection it is often atypical. It may be loculated, nondependent, or interlobar and often requires more than one drainage. However the use of the drug decreases the incidence of empyema, and if thin fluid forms it may be sterilized without the formation of thick pus. The local use of the sulfa drugs is of questionable value.

Next to the pneumonia as the primary cause of the pleural infection is the intra abdominal suppuration with subdiaphragmatic abscess and, later on supradiaphragmatic extension. The organism here is often the colon bacillus.

The treatment of empyema with penicillin is not yet entirely standardized but the experience to date is sufficient to lead to certain conclusions which however may need to be revised at a later date. The best chances of success are in the early thin effusions before frank pus is formed. Of course, the type of organism and its vulnerability to penicillin are the main factors which will determine its successful use. Both parenteral and local use should be resorted to as parenteral use alone does not give high enough concentrations in the pleural cavity. Five hundred units per cubic centimeter is the concentration for local instillation. The pus should first be aspirated and one half that volume of penicillin used for replacement.

Once frank pus is formed, drainage is usually required as thick pus and fibrin masses cannot be aspirated. Even though the cavity may be sterilized there remains the thickened pleura and fibrosis which lead to chronic empyema. Cases of penicillin failures are illustrated.

The development of bronchopleural fistula as a complication of empyema is a serious one and may lead to months of convalescence. When the x ray film demonstrates a fluid level and when air has not been allowed to enter the pleural cavity a fistula must be assumed to be present. Early recognition is important, as closed drainage will often cause a spontaneous closure of the fistula. In cases in which the fistula does not close the morbidity is high and chronic empyema usually results. For such cases Blades is quoted as using a decortication operation through an intercostal incision, and the incision is closed tightly with closed catheter drainage and suction. The released lung may be readily expanded and caused to adhere to the parietal pleura. Should the fistula reopen it is of relative unimportance as the lung has adhered to the thoracic wall.

FORESTER D. DOORLEY, M.D.

HEART AND PERICARDIUM

Niklin, D. C.: Wounds of the Heart. *Ann. Surg.*, 1944, 120: 87

This report concerns the operative treatment of 23 cases of wounds of the heart, or intrapericardial portions of the great vessels. There were 5 deaths in this series, a mortality of 22 per cent, as compared with a 42 per cent mortality in a previously reported series of 38 similar cases. In the present series there were no deaths from infection. Those patients who did not recover either died on the operating table, or shortly after operation, presumably from hemorrhage or the effects of tamponade. The reduction in mortality from infection was not due to the use of sulfa drugs, since they were used in only 1 case for the treatment of postoperative pneumonia. In no instance was a sulfa drug placed in the wound. The reduction in infections is believed to be the result of more careful preoperative preparation and a more meticulous technique. Another possible factor is the lowered mortality has been the giving of intravenous fluids to the last 8 patients prior to operation. This treatment was based on experimental evidence that rapid intravenous infusion with subsequent increase in the blood volume, enables a dog to withstand a considerably higher intrapericardial pressure. In each patient receiving intravenous infusions there was clinical improvement preoperatively.

The indication for operation in all cases was the finding of definite evidence of cardiac tamponade. This diagnosis was based on lowered arterial and increased venous pressure, and the presence of a quiet heart on fluoroscopic examination. The latter finding is the most important sign and the one least likely to lead to a mistaken diagnosis. Venous pressure readings are not only of value in the diagnosis of tamponade but are of considerable prognostic importance. If the venous pressure is high, that, in itself, is evidence that the heart is carrying on its functions and that the cardiac output is at least sufficient to produce such pressure. On the other hand, a low or lowered venous pressure in the presence of tamponade is evidence of a failing heart and a greatly reduced cardiac output. In 17 patients arterial pressure was so low that it could not be recorded. In those patients who recovered there was an immediate rise in arterial pressure following the release of the tamponade. Some type of general anesthesia in which positive pressure can be used is preferable to local anesthesia, since the difficulties of heart suture require that the patient be quiet throughout the procedure.

The author has slightly modified his previous opinion that operation should always be performed as soon as the diagnosis of a heart wound is established. Delay is justified if continued improvement follows aspiration without recurrence of signs of cardiac compression, but operation should not be delayed if there is evidence of bleeding into the pleural cavity or through the external opening. In this series, all patients had immediate opera-

tabulated summary of the data on the 23 cases is presented.

JOHN L. LINDQUIST M.D.

Vódice, A.: The Surgical Treatment of Cardiac Syncope, Apparent Death, Cardiac Fibrillation, Stoppage of the Heart (*Tratamiento quirúrgico del síncope cardíaco. Muerte aparente, fibrilación cardíaca, paro cardíaco*). *Rev As méd argent.*, 1944, 53: 937.

During operation with any kind of anesthesia, cardiac syncope may occur. The heart beat stops and there is no arterial circulation. This condition may result from ventricular fibrillation or stoppage of the ventricle. The pressure falls to zero. The patient is apparently dead, although prompt action may restore the heart beat. The brain cannot endure deprivation of the blood supply for more than from two to five minutes and therefore action must be very prompt. Every second counts. Efforts are being made to find some means of preserving cerebral function for a longer time but so far they have not been successful. Experiments in producing artificial fibrillation in animals and then treating it have contributed to the successful treatment of this condition in human beings.

In every operating room the apparatus for treating stoppage of the heart should be at hand. If the heart stops the anesthetist should give artificial respiration to keep up the oxygenation of the lungs, while the surgeon should expose the heart by opening the pericardium and massage the heart with a rhythm of from 50 to 60 movements per minute. After the flabbiness of the heart muscle has been overcome and the beat restored, electrical shock should be given for the purpose of overcoming the fibrillation. The apparatus used for this purpose is illustrated and the technique of the shock described in detail. The shock may be applied 3 or 4 times, or even more if necessary. Patients apparently dead have been restored in this way. Illustrative cases are described.

Supplementary methods are the pouring of 2 cc. of a 5 per cent solution of procaine over the heart before the massage and the injection into the cavity of the right ventricle of 1 cc. of a 1:1000 solution of adrenalin diluted in from 10 to 30 cc. of physiologic salt solution, if massage does not prove effective at first.

AUREY G. MORGAN M.D.

ESOPHAGUS AND MEDIASTINUM

Rankin, L. M.: Perforated Ulcer of Esophagus Following a Burn. *Am. J. Surg.*, 1945, 67: 134.

In 1843 Curling first described duodenal ulcer following a burn. The cause and frequency of this complication are still uncertain. Ulceration of the lower end of the esophagus following a burn is even more rare. A search of the literature revealed only 1 case of perforation of such an esophageal ulcer.

The author presents the case of a four-year-old boy who sustained second-degree burns of both thighs, buttocks, and the lower abdomen. The child progressed very well for four days. He then sud-

Fig. 1. The lower end of esophagus and stomach showing perforation of ulcer of esophagus. (Courtesy of American Journal of Surgery)

denly developed severe pain, following which his condition became worse, and he died within two hours. Autopsy revealed a perforated ulcer of the lower end of the esophagus with hemorrhage (Fig. 1).

No case has been reported in which surgical closure has been attempted, but this gives the only hope for cure.

THOMAS F. THORNTON, JR. M.D.

Hurst, A., and Bassett, S.: Megacosophagus as a Cause of Mediastinal Widening. *Am. J. Roentg.* 1944, 52: 508.

This report deals with 11 cases in which the initial roentgenogram of the chest suggested the presence of a megacosophagus, which was subsequently verified by a barium meal. They were discovered in extensive mass surveys of apparently healthy adults to detect unknown cases of tuberculosis. Nine patients were males, inasmuch as the majority were rejected draftees. One of the most interesting features in the study of megacosophagus is the marked disproportion between the relative paucity of the complaints and the good general condition of the patient on the one hand, and the large size of the esophagus on the other. No benign or malignant

stricture causes dilatation even approaching that produced by "cardiospasm."

Five diagnostic roentgen features were found, as follows:

1. Diffuse widening of the mediastinum. The shape depends largely on the degree and location of the dilatation. The widening of the mediastinum is usually seen beginning at the thoracic inlet or just below. The degree of widening is difficult to measure since the largest dilatation is to the right and the left border is lost in the density of the heart shadow.

2. A definite fluid level was found in 4 of the 11 cases traversing the tracheal column of air at the level of the clavicles. This depends for its presence on recent drinking or eating, but if present is pathognomonic.

3. In the upper esophagus lying to the right of the sternum, there is occasionally seen a peculiar stippled, marbled or mottled density. This is due to the contrast created by the mixture of air and food contents. It was seen in 4 of 11 patients.

4. All but one case showed apparent widening of the cardiac contour on the right. Greater exposure reveals an apparent reduplication of the cardiac contour.

5. In all cases the dilated esophagus, after following the cardiac contour crossed to the left and obliterated the cardiophrenic angle.

In suspected cases complete roentgen studies with barium should be made to differentiate this condition from congenital anomalies involving the esophagus and stomach.

THOMAS F. THORNTON, JR., M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Muñoz, F., Vega, T., Morales, E., Rodríguez, A., and Díaz, A. R. Total Gastrectomy; a Clinical and Physopathological Study *Gastroenterology* 1944, 3 380

Thirteen total gastrectomies were done by the authors during the period from 1941 to 1944 in Mexico. The effects of total gastrectomy are briefly stated following studies on 4 of their patients who survived long enough to be in a good general condition. Comments are made only on results as a whole and the details are omitted. The immediate post-operative mortality was 27 per cent. The total mortality in cases of malignancy was 91 per cent within a period of one and a half years after operation. The average duration of life was ten months. One patient is still living after three years.

The authors consider total gastrectomy for malignancy only in well selected cases. The most favorable lesion is the linitis-plastica type of carcinoma, without metastasis in a middle-aged patient in good general condition. High lesser-curvature ulcers are also suitable for total gastrectomy. Absence of metastatic involvement is necessary. The resection must be total, with the cardia and pylorus visible in the specimen.

The authors are now more pessimistic than they were when they began this type of treatment and believe that the average survival period is not longer than one year which does not sufficiently reward the patient for his effort. In their experience, in general it is advisable to perform subtotal partial gastrectomy for the surgical treatment of cancer.

The physiopathological results in total gastrectomy are shown in table 1 in a review of their 4 cases. The chief disturbance which follows total gastrectomy is motor in character. The general metabolism is preserved and the mineral metabolism is only slightly affected. Anemia may occur especially the hypochromic type. Attention must be given to the diet and pharmaceutical measures to protect the nutrition.

EMIL C. RONTSEK, M.D.

Flemby W. R.: Peptic Ulcer in the Canadian Army (1940 to 1944). *War Med.* Chic., 1944 6 300.

In this report on the dyspeptic syndromes in the Canadian Army gastroduodenal disorders accounted for only 1 per cent of the total admissions to the hospital but they utilized one-eighth of the beds in the medical inpatient division. Only patients with respiratory tract disease were more numerous among hospital admissions.

An accurate diagnosis among recruits was difficult because only fifteen minutes were available for clinical examination. Even with this limited time the per cent of error was only 12 as revised by x ray

study. The length of the history was not always helpful because some patients had very short histories—one being only five days. Psychoneurotics, morons, and malingers made an accurate diagnosis difficult, malingers being the most troublesome.

At first an attempt was made to return men with healed duodenal ulcers to active duty but only 8 of 70 such patients could remain on duty in England. Then an attempt was made "to determine how healed peptic ulcer patients would be able to carry on with some duty in Canada." This study showed that some 10 per cent of these men could remain on active duty. Two factors were important in their ability to do this (1) willingness to continue in service and (2) the ability to select food and environment. It was interesting to note that officers and noncommissioned officers made up half of this group.

Gastric ulcers made up 7 per cent of the total and all of the patients with healed gastric ulcer were unable to continue on duty in England which necessitated ultimate discharge from the service.

From this study the author has concluded that the incidence and significance of peptic ulcer in the army have been overestimated, and that the cause for this is the failure to recognize that military hospitals classify their patients into medical and surgical groups. In addition large outpatient clinics are also conducted. Both parasitic and traumatic illnesses exceed gastrointestinal disease in importance. The author recommends that patients having perforation or hemorrhage be excluded in order to reduce pension responsibility. Moreover, the treatment of peptic ulcer should be undertaken in special units. Segregation of these patients provided a most economical and satisfactory method for their care. The author's final conclusion was as follows: The usefulness of persons suffering from peptic ulceration, whether they are with the armed forces or in civil occupations, is limited. They have a disease which causes serious wastage of man hours and enough misery to warrant the best study possible.

SAMUEL J. FOGELSON M.D.

Hunt G. H., and Bowden J. N.: Rupture of Intestine Caused by Nonpenetrating Trauma of the Abdominal Wall: A Report of Cases. *Arch. Surg.*, 1944 49 331

This report of 6 cases of rupture of the intestine caused by nonpenetrating trauma of the abdominal wall is principally concerned with the results of relatively minor trauma. With the type of injury considered there is likely to be an interval of several hours during which abdominal symptoms are minimal and signs confusing. The symptoms are those of peritonitis, which develop with variable rapidity according to the site of perforation the composition of the leaking intestinal contents and the amount of leakage. Shock is generally not an outstanding fea

ture in these cases but some pain is usually present from the beginning. The two important points are (1) keeping the possibility of intestinal perforation in mind following even minor trauma, and (2) prompt exploration of the abdomen at the first sign of peritonitis. The operative procedure is planned to permit thorough exploration of the entire small intestine since most perforations occur in the jejunum or ileum. If a perforation is found it should be covered with a warm, moist sponge and possible multiple perforations sought.

Six cases are reported in detail. In one of these the intestinal perforation was complicated by other serious injuries which masked the abdominal symptoms and precluded exploratory operation after abdominal symptoms did appear. Another case was accompanied or caused by penetrating trauma. In 4 cases of uncomplicated rupture of the intestine by nonpenetrating abdominal trauma, the mortality rate was 25 per cent in all 6 cases the mortality rate was 33 per cent.

JOHN L. LINDQUIST, M.D.

Spelman, A. E.: Healing of Intestinal Anastomosis. *Am. J. Surg.*, 1944, 66: 309.

The author reports the results of his studies and describes the essentials of the process which establishes continuity of the gastrointestinal tract following either the suture of wounds or an anastomosis. The more common factors causing failure are also presented. The material consisted of pyloric resections, gastroenterostomies, and intestinal anastomoses performed on more than 100 dogs. Serosa-to-serosa approximation by suture was performed on more than 50 rabbits. Varying techniques were used in suturing; some specimens received meticulous aseptic care, others being contaminated with bowel contents. This investigation was further limited to the following procedures: (1) those accomplished without contamination by virulent organisms; (2) those in which unattenuated organisms may produce infected areas; and (3) those attempted in the presence of a deficient blood supply.

Healing was studied after the intestines were sutured with one continuous silk or chromic catgut inverting stitch, including the mucosa, muscularis, and serosa. Another silk stitch included the serosa only.

When the gut wall is inverted by suturing, a triangular chink is formed just outside of the line of anastomosis on the serosal side. Within fifteen minutes fibrillar fibrin begins to form in the exudate which binds the surfaces together and makes them watertight.

During the first few days following the anastomosis there is hyperemia, general edema, and cellular infiltration in the tissues of the sutured area. This leads to tissue which pushes the serosal surfaces into closer approximation, and thus aids in the closing of the chink along the line of anastomosis. The general swelling enlarges the volume of tissue and by its size may produce a brawny thickening of the ring, which causes partial occlusion of the lumen. After a week

the swelling begins to subside and in another ten days it has largely disappeared.

Infection with virulent organisms causes granular fibrin to form. The wound may be temporarily sealed by the granular fibrin but before permanent union of the tissues takes place, it undergoes resolution and the tissue surfaces are freed. The wound then may be easily pulled apart and may leak if the suturing and consistency of the tissue is not sufficient. This dissolution of union occurs most often between the sixth and eighth days.

When the circulation to the stomach was impaired and a posterior Polya type of anastomosis was made in dogs, they recovered from the operation and improved rapidly until, by the fifth day their condition appeared almost normal, then invariably the animals died rather suddenly between the sixth and eighth days.

A study of specimens of this type showed that within twenty-four hours the exudate and fibrillar formation were present, but the latter soon underwent resolution as necrosis developed in the ischemic area.

This study therefore demonstrates that the most tangible aids in establishing a watertight anastomosis were fibrillar fibrin, lack of contamination with virulent organisms, and an adequate blood supply to the area of anastomosis. Every effort should be made to avoid localized areas of ischemia, particularly when the blood supply has already been decreased.

SAMUEL J. FOGELSON, M.D.

Anderson, S. G.: A Statistical Survey of Appendicitis in Children. *Med. J. Australia*, 1944, 2: 597.

An analysis is presented of 933 cases of acute appendicitis treated at the Children's Hospital, Melbourne, between 1931 and 1943. Fifty-five patients were under the age of three years (younger age group) and 878 patients were between the ages of three and fourteen years (older age group).

Complications of abscess or peritonitis were present in 75 per cent of the 55 patients under the age of three years, and in 30 per cent of the 91 patients between the ages of three and six years.

In the younger age group 68 per cent of the patients had temperatures over 102°F., and in the older age group 13 per cent registered fever of this degree. Twelve patients in the older age group with appendiceal abscess or general peritonitis, and 103 patients with acute appendicitis had normal temperatures on admission.

Vomiting preceded abdominal pain in the majority of the patients in the younger age group whereas abdominal pain was the first symptom in the older age group.

Sixty-five per cent of the patients in the older age group were hospitalized for less than ten days, and 32 per cent were in the hospital for more than ten days. Infection of the wounds was the cause of prolonged convalescence in 83 per cent of the cases.

Infection of wounds was studied in 185 consecutive patients in whom this complication occurred,

and in the majority of these (153) there was some degree of peritonitis at the time of operation. Non-purulent fluid was present in the peritoneal cavity in 17 patients, and intraperitoneal drainage resulted in infection of the wounds. This was in contrast to many similar cases in which the abdomen was closed without drainage and without subsequent infection of the wound. In the cases in which there was some degree of purulent peritonitis at operation the smallest percentage of infections of the wounds was noted among the patients in whom the abdomen was closed without drainage—17 per cent of wounds were not infected after intraperitoneal drainage compared to 48 per cent after no drainage.

The mortality figures were as follows:

Children under three years of age	No.	Deaths
Type of Condition		
Acute appendicitis	14	0 (0%)
Acute appendicitis with abscess or peritonitis	41	16 (39%)
Children over three years of age	378	24 (3%)

Twenty two of these deaths occurred in cases complicated by peritonitis or appendical abscess.

In the younger age group a study was made of the mortality in cases complicated by peritonitis or abscess. Of the 11 patients with peritonitis 4 died (36 per cent). There were 18 abscesses, and in one half of the patients the operative technique involved disturbance of the localizing barriers, with 6 deaths (67 per cent); in the remaining half the operative disturbance was minimal (2 appendices not removed) and there were no deaths; the operative findings were inconclusive in the remaining 12 cases.

The influence of sulfonamide drugs as an adjunct in treatment was inconclusive because of the small number of cases in which they were employed.

ERNEST E. ARNHEIM, M.D.

Moreno, I. G.: Transperitoneal Fixation of the Kidney and Colon (Nefrocolonfijación transperitoneal). *Rev. Acad. argent. cir.* 1944, 28: 1063.

The author in collaboration with Russo has operated by the transperitoneal route for fixation of the prolapsed kidney and colon. The patients were between twenty five and thirty years of age and mostly women. Nine of them returned for examination, and a number of pyelograms made before and after operation are shown. The case histories are given. In 90 per cent of the cases all symptoms disappeared. No patient was made worse by the operation. In 50 per cent of the cases there was no constipation before operation, and 90 per cent of the existing constipation in the remaining cases was corrected. Increase in weight after the operation varied from 5 to 13 kgm. Elevation of the kidney was not brought about in 2 cases, but the patients were cured of their symptoms. There was a moderate lifting of the colon in all the cases.

The operations were performed by the technique of Alberto Gutiérrez. It was found, however, that when the quadratus lumborum and psoas muscles

were sutured vertically the muscles tore easily; therefore, they were sutured transversely and to include a large amount of muscle in the suture. Other wise the kidney overcomes the suture and becomes displaced again. The appendix can be removed at the same time as it sometimes plays a part in causing the patient's symptoms. The author believes that more can be accomplished by the transperitoneal route in this condition than can possibly be accomplished by the lumbar route, and that this operation is infinitely superior to any of the other operations proposed for prolapse of the kidney and colon.

AUDREY G. MORGAN, M.D.

Mackenzie, D. H.: Sulfasuxidine in Operations on the Rectum and Colon. *Brit. M. J.* 1944, 2: 722.

Various workers have shown that the administration of succinyl sulfathiazole (sulfasuxidine) causes profound changes in the stools of the recipient, the principal change being a marked decrease in the gram negative organisms of the intestine as shown by colony counts and by the study of films.

In connection with the surgery of the rectum and colon some investigations have been made to determine the action upon the intestinal organisms of sulfasuxidine, sulfaguanidine and sulfathiazole. The technique used was that of Holt and Wright, namely, 0.5 gm. of feces was thoroughly mixed with 4.5 cc. of nutrient broth and serial dilutions were made up to 10^6 . One standard loopful of each dilution was plated on to selective media—MacConkey and desoxycholate citrate agar. Colony counts were made after twenty-four hours at 37°C. Films were examined wet and with Gram's stain.

The author investigated 30 cases. These were studied as follows:

3 cases received 20 gm. per day of sulfasuxidine	
5	10 gm.
8	10 gm. sulfaguanidine
6	2.5 gm. sulfathiazole
8	5 gm.

An account of the results is given. They were remarkably consistent. In the cases receiving 20 gm. per day of sulfasuxidine colony counts and studies of films showed a universal decrease in gram-negative organisms. In cases receiving 10 gm. per day the sterilization was less consistent and more time was required to effect an adequate reduction in gram-negative organisms. The dosage of 5 gm. per day appeared to be ineffective.

The action of sulfaguanidine in no way compared with that of sulfasuxidine, with the exception of the abolition of pathogenic nonlactose fermenters. Even after five or six days' treatment there was frequently a confluent growth of coliform organisms when the 10^4 , 10^5 and sometimes the 10^6 dilutions were plated out.

The use of sulfathiazole as a preoperative treatment has certain obvious disadvantages. It is more likely to cause toxic symptoms than either sulfasuxidine or sulfaguanidine and is far more likely to give rise to renal complications. However even with the

small doses given in these experiments, there was a greater effect than that obtained with sulfaguanidine. There was a decline in gram-negative organisms, and with a dose of 5 gm. per day it was common for bacillus-coli colonies from the 10^2 dilution to number less than 20.

From these studies the author concludes that a dosage of 20 gm. of sulfasuxidine per day for four days before operation as a preoperative treatment, is satisfactory

MATTHEW J. SKIFFERT, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Timoney, F. X.: Cholecystitis. The Advantages of Operative Treatment in Definite Unmistakable Disease. *Am. J. Surg.* 94:5 67:57

Of the 151 patients with cholecystitis treated by the author 90 were female and 61 were male. Seventy-six per cent of the patients were in the thirty to sixty year age group. A reasonably high degree of diagnostic accuracy was obtained. The diagnosis was correct in all but 7 cases. This can be attributed to the presence of x-ray evidence of stone, repeated nonfilling of the gall bladder during cholecystography or the history with symptoms and definite physical signs of an acute attack.

Cholecystectomy was the operation of choice in more than 90 per cent of the cases. Six per cent of the patients required drainage of the common duct. The outstanding indications for common-duct drainage are palpation of stones, a history of jaundice, multiple small stones in the gall bladder with a dilated cystic duct, dilatation of the common duct, and enlargement of the head of the pancreas.

Operations performed in the presence of unmistakable gall bladder disease give assurance of increased satisfactory results. This is the result of more strictly limiting the indications for operation. The presence of gall stones or the history or presence of an acute attack make reasonably certain indications for operation. The operative mortality for unmistakable gall-bladder disease can be kept to a low figure.

SAMUEL KANE, M.D.

Mirizzi, P., and Urrutia, J. M.: Sequelae of Cholecystectomy (Secuelas de la coledocistomía). *Rev. Med. Rio.* 944, 26 501

This is a study of cases in which symptoms recurred after cholecystectomy. It is based on the operations performed by the authors in the past ten years and 1,000 operations performed elsewhere. Graphs show the facts on which their conclusions are based.

They found that cholecystectomy gives complete cure in 95.8 per cent of the cases, and that there are serious sequelae in 1.6 per cent and milder sequelae in 2.6 per cent. Most of the serious sequelae are due to residual stones in the common duct that have been overlooked on operation. Those of lesser seriousness are most frequently caused by spastic disturbance of the sphincter of Oddi and pancreatitis.

Infection is a secondary and not a primary cause of the postoperative symptoms. It aggravates rather than produces the difficulty. Residual hepatitis is not an important factor in causing postoperative symptoms. It generally improves automatically after the cholecystectomy. Adhesions may cause serious sequelae but there are not many cases in which they are the only cause of the disturbance.

Surgical treatment should be complete in the first operation. Repeated operations are always more difficult and dangerous than the first operation. The best means of preventing the overlooking of any stones is by the use of operative cholangiography that is, the taking of roentgenograms of the bile tract during operation. These are much more reliable than roentgenograms taken before operation and make accurate diagnosis possible in 99.5 per cent of cases thus they reduce unpleasant sequelae to a minimum.

ARMSTRONG G. MORSE, M.D.

Schena, A. T.: Rupture of the Common Duct after Cholecholestomy (Ruptura del coledoco postcoledocostomía). *Bol. Acad. argent. cir.*, 1944, 25 390.

Rupture of the scar in the common duct after drainage for infection is rare. Only 5 cases have been described previously in the world literature and the author adds a ninth, on which he operated. The patient was a woman of forty-eight who about a year previously had been operated on for biliary lithiasis, the gall bladder was removed and the common duct drained with a Kehr tube. On the recurrence of symptoms she was operated on by the author and a residual stone was removed from the common duct and drainage again established with a Kehr tube. The tube remained in for a total of thirteen and one half months. Some six months after removal of the tube signs of peritonitis developed and operation showed that infected bile was flowing into the peritoneal cavity from a rupture of the operative opening in the common duct. The pus was encysted, partly because of the presence of adhesions from the former operation and the patient recovered.

The factors that bring about rupture of a cholecholestomy scar are increased pressure within the duct and infection, which softens the cicatricial granulations and makes them friable. There may also be digestion of the tissues from activation of the pancreatic reflex, but there was no history of pancreatitis in this case.

The question of how long a Kehr tube should be left in place after a cholecholestomy is a disputed one. Carter in 1936 published a review of the opinions of North American physicians. Judd said that the tube should remain in place as long as there are any signs of infection and that it does no harm if it remains for months. Schena held that the time should be determined by postoperative cholangiography and the functional tests of Bengtson.

In the discussion Allende said that the probable cause of the rupture was excessive denudation of the common duct during the operation, which deprived the wall of its vessels and led to mortification. This

may occur when it is difficult to free the common duct from a dense inflammatory infiltration and it is particularly apt to occur when a second operation is to be performed as in this case.

AUDREY G. MORAN, M.D.

Martorena, L. H.: Tumor of Vater's Ampulla. Duodenopancreatectomy in One Stage (Tumor de la ampolla de Vater: duodenopancreatectomía en un tiempo). *Boletín Acad. argent. chir.* 1944, 38: 1042.

A safe technique for duodenopancreatectomy with ligation of Wirsung's duct was not devised until 1935. The author describes a case of tumor of Vater's ampulla in a man of forty three who for eight years had had attacks of alimentary intoxication. Followed by a very severe one with intense itching, icterus and acholia he came for treatment. There was a palpable swelling in the right hypochondrium.

Operation showed a lobulated tumor in the head of the pancreas extending back of the mesenteric vessels and connected externally with the wall of the second part of the duodenum. Removal of the tumor after ligation of the vessels, and duodenopancreatectomy with suture of the stump of the pancreas with chromicized catgut were done. The steps of the operation are illustrated. The patient's condition improved under the administration of hypertonic glucose solution, the transfusion of blood and injections of vitamin K. As a substitute for the pancreatic secretion he was given takadlastase and peptopancrease. The pancreatic fistula continued to drain for twenty-seven days and was completely closed forty days after the operation. Histological examination showed adenocarcinoma grade III of Vater's ampulla, adenocarcinoma of the pancreas, and metastatic adenocarcinoma of a retropancreatic gland.

When tumors of Vater's ampulla grow into the lumen of the duodenum they can be removed transduodenally. Among the 126 operations of this kind, 103 were performed before 1935 with a mortality of 33 per cent, and 23 were done since that time with a mortality of 17 per cent. Twenty two of the patients survived three years or more. When the tumor is of the ulcerous type it often invades the inner wall of the duodenum and the head of the pancreas and necessitates duodenopancreatectomy. This operation was formerly performed in two stages but is now performed in one stage when the condition of the patient permits.

The dangers are pancreatic biliary or duodenal fistula and the risks due to the loss of pancreatic juice. The pancreatic fistula often closes spontaneously but if it does not do so in a few weeks the stump of the pancreas should be implanted into the intestinal tract most frequently into the stomach. The biliary fistula shows little tendency to close spontaneously and the best treatment is to anastomose the common duct with the intestine. So far as has been observed from 80 to 85 per cent of the fat ingested is absorbed in man after loss of the pancreas. Definite conclusions as to the effect of the loss of pancreatic juice cannot be drawn until a number of

patients have survived the operation for five years or more.

AUDREY G. MORAN, M.D.

Mirizzi, P. L.: Biliary Lithiasis and Pancreatic Disease. A Contribution on Operative Cholangiography (Litiasis biliar y pancreopatia. Apporte documental de la colangiografía operatoria). *Prensa med. argent.* 1944, 31: 2241.

There is a very close relationship between biliary lithiasis and disease of the pancreas. Among 1,278 cases of acute pancreatitis reported by Schmieden and Sebening there was disease of the biliary tract in 894, or 70 per cent. Statistics reported by other authors give about the same proportion. This relationship is brought about by dystonia of Oddi's sphincter which results in the reflux of bile into Wirsung's duct, or conversely of pancreatic secretion into the bile tract.

Biliary lithiasis is a prominent factor in the causation of acute and chronic pancreatitis and, conversely the reflux of pancreatic secretion into the bile tract is a factor in the etiology of such diseases of the bile tract as perforation of the gall bladder, exfoliative cholecystitis, and biliary peritonitis. It is not the presence of the pancreatic secretion in the bile tract itself that causes the trouble but the fact that it changes the reaction of the bile from acid to alkaline and thus makes it a good medium for activating trypsin to the point where it digests the tissues.

This flow of fluid from the one system to the other can be demonstrated by operative cholangiography that is, the injection of lipiodol into the cystic duct or vestibule followed by the taking of roentgenograms. These demonstrate the reflux.

Cases of the various diseases of the bile tract and pancreas caused by this reflux are described and illustrated.

AUDREY G. MORAN, M.D.

Young, H. B.: A Case of Accessory Pancreas in an Unusual Position Complicated by Acute Necrosis. *Glasgow M. J.*, 1944, 142: 156.

A thirty six year-old male was operated upon for a suspected perforated ulcer. For three weeks he had had midepigastric pain of a stabbing type passing through to the back. This was accompanied by nausea and vomiting. On the day of admission to the hospital he suddenly developed very severe generalized abdominal pain. The abdomen was held rigid.

At operation a firm mass was found in the gastrotrophic omentum along the lesser curvature of the stomach but completely separate from this organ. The mass was the size of a walnut, irregular firm but not stony hard, and unconnected with any other structures. The lesser omental bursa was explored and found to be normal. The pancreas was not unduly hard or irregular.

A biopsy of the tumor mass was proved to contain pancreatic tissue including islets of Langerhans. There were areas of necrosis. The final diagnosis was infection of an accessory pancreas.

EARL O. LATIMER, M.D.

Miller J. M., and Wiper T. B.: Physiological Observations on Patients with External Pancreatic Fistula. *Ann. Surg.* 1944, 70: 852.

During the past ten years there have been only rare reports appearing in the medical literature of physiological observations made upon human subjects with external pancreatic fistula. The fundamental information concerning pancreatic function has been derived from the experimental laboratory animal, on which with painstaking care the fundamentals of pancreatic secretion have been investigated. Rarely has the clinician been given the opportunity to correlate the physiological observations made upon the human being with the results obtained from the experimental animal. The recent advances made in the operative attack upon lesions of the pancreas make it imperative that the surgeon be more conversant with the physiology of that organ for interference with the normal flow of the external secretion will result in profound alterations in the total metabolism.

A rare opportunity was offered to make observations on the influence of such persistent fistulas upon these patients, particularly with reference to the many alterations induced. The observations included

- (1) the general nutritional state of the patient
- (2) the total pancreatic flow in twenty-four hours
- (3) the pattern of flow in a twenty-four-hour period
- (4) the plasma-electrolyte pattern
- (5) the plasma protein
- (6) the influence of water intake on the pancreatic flow
- (7) the observations on volume flow alterations induced by the administration of various substances into the duodenum
- (8) the effect of intravenous fluids upon the pancreatic secretion and
- (9) observations on volume flow alterations induced by the subcutaneous administrations of drugs.

They are reported in detail in a statistical study presented in this article.

Pancreatic flow is continuous throughout the twenty-four hour period and is influenced, to great degree, by the state of hydration of the individual. One pancreas produced 1,770 cc. of fluid in a twenty-four-hour period. Attention was drawn to the marked alteration in water balance plasma-protein level, and plasma electrolytes, with special emphasis upon plasma sodium in patients with severe external pancreatic fistula. It was emphasized in this presentation that the sodium loss in severe pancreatic fistula produces a clinical syndrome similar to that described by Addison, with the exception that adrenal disease is not present. This analogy has not been stressed previously. The administration of adequate amounts of sodium and water in the presence of sufficient plasma protein to hold them in the circulation alleviates the symptoms peculiar to this syndrome.

Diminution in pancreatic secretion through the fistula may be obtained by the administration of a number of drugs. However ephedrine and sodium bicarbonate are the most practical of these because of the unpleasant or deleterious side-effects of the

others. Pancreatic secretion is markedly stimulated by the intramuscular administration of histamine, and by the intravenous administration of physiological saline solution or 5 per cent glucose in physiological saline solution.

Detailed physiological observations upon pancreatic function were recorded. Certain of these observations contribute definite support to the theory that secretin secretion is a filtration process. These are

1. Sodium ion is present in equal amounts in both blood plasma and pancreatic secretion.
2. The total of the concentrations of chloride and bicarbonate ions are the same in blood plasma and pancreatic secretion.
3. The same amount of ionizable calcium is present in blood plasma and pancreatic secretion.
4. Sulfanilamide is found in the same amount in blood plasma and pancreatic secretion.

Large amounts of ionizable calcium are normally returned to the gastrointestinal tract through pancreatic secretion. This phenomenon has not previously received the recognition it warrants.

The appearance of sulfanilamide in therapeutic concentration in pancreatic secretion suggests its use in acute inflammatory disease of the pancreas.

JOHN E. KIRKPATRICK, M.D.

Erb, W. H.: Radical Pancreatoduodenal Resection for Adenocarcinoma of the Head of the Pancreas. *Surg. Clin. N. America*, 944, 24: 1370.

The development by Whipple, Brunschwig, and others of a surgical technique for the radical removal of carcinoma of the head of the pancreas necessitates an earlier diagnosis so that more and more cases may be found to be operable at laparotomy. With this in mind, the author charted laboratory data, histories, symptoms, and physical signs to aid in the differential diagnosis of surgical and nonsurgical jaundice of the hepatocellular variety. The diagnosis of hemolytic jaundice is usually sufficiently clear, and it is not included in the tables. If a definite diagnosis cannot be made, then surgical exploration is indicated. If the lesion is not surgical the harm to the patient can be kept at a minimum with adequate preoperative preparation and continuous spinal anesthesia.

A woman, aged fifty-two years, had been well until a year before admission, at which time she began to complain of vague indigestion and gas pains. There was no recent history of jaundice or of pruritus. The Graham-Cole test sixteen hours after oral administration of dye failed to show any evidence of a gall bladder shadow. The patient's clinical history and the presence of a small extrinsic pressure defect on the duodenal cap aroused the suspicion of early malignancy of the pancreas or common duct. Examination at this time revealed a mild icterus and a palpable mass in the region of the gall bladder. The Van den Bergh test was immediately direct, the icterus index 30 units, and the quantitative serum bilirubin 1.4 mgm. per 100 cc. of serum.

Under continuous spinal anesthesia, a laparotomy was done through a right rectus incision. A greatly distended gall bladder and common duct were exposed. A mass which appeared movable was felt in the head of the pancreas. The distended gall bladder interfered with exposure therefore it was drained of normal-colored bile. A radical resection in one stage was decided upon. The stomach was divided proximal to the pylorus and closed. The duodenum was fixed and divided 5 cm. distal to the lesion. The common duct was isolated, ligated, and divided. The closure was reinforced by interrupted sutures of silk. The body of the pancreas was then bisected 3 cm. from the lesion. Two distended ducts were separately ligated and the pancreas was turned in with silk.

The head of the pancreas was markedly adherent to the portal vein and had to be freed from it by sharp dissection. The jejunum could not be brought in contact with the gall bladder without tension, probably because of the marked scoliosis, but as the distal end of the duodenum was readily available the author made an anastomosis between the gall bladder and the duodenum. Silk was used for the serosal layer and catgut for the mucosal, in all the anastomoses. Following this a routine retrocolic, posterior gastrojejunostomy was done. Two cigarette drains were placed next to the bisected pancreas and brought out through a stab wound. The peritoneum was closed with catgut the anterior rectus sheath with catgut and tension sutures of wire, and the skin with wire. The patient received 500 cc. of blood and 800 cc. of normal saline solution on the table.

The pathological report was adenocarcinoma of the pancreas.

Fig. 1. Left, Schematic drawing showing points of division as described in the operative note.

Fig. 2. Schematic representation following anastomosis. The pancreas and transverse colon are not shown for the sake of clarity.

The postoperative course was smooth. Starting on the third postoperative day and lasting until the twelfth postoperative day there was profuse drainage from the stab wound of what was assumed to be pancreatic juice. No bile was ever noted in this drainage. The patient was discharged from the hospital on her twenty third postoperative day.

The author concludes that permanent cure of carcinoma of the head of the pancreas will follow the successful resections only rarely. The anatomic position of the pancreas adjacent to vital structures (portal vein) which cannot be sacrificed prevents one from doing a wide resection of the growth. However life expectancy can be increased as in this case in spite of the fact that the pathologist found the tumor at the very edge of the resected tissue.

JOSEPH K. NARAT, M.D.

GYNECOLOGY

UTERUS

Chaffin, R. C.: *Procidentia. The Chaffin Vaginal Subtotal Hysterectomy for the Cure of Fourth Degree Prolapse; Review of Technique and Results.* *Am. J. Surg.* 1944, 66: 338.

The author prefers the Watkins-Wertheim interposition operation for the correction of cystocele associated with minor degrees of uterine prolapse. He describes an operation devised to remedy more severe grades of prolapse associated with uterine, bladder and cul-de-sac protrusion. The cervix is treated with the Percy cautery if indicated. A supracervical hysterectomy is then performed by the vaginal route, and the severed ends of the round and broad ligaments are sutured into the lower posterior surface of the cervix or into the cul-de-sac itself. The retained cervix is sewn to the pubovaginal fascia to obliterate the opening through which the bladder protrudes and the operation is completed with a perineorrhaphy.

GROVER BUNNEX, M.D.

Macfarlane, C., Sturgis, M. C. and Fetterman, F. S.: *The Value of Periodic Pelvic Examination in the Control of Cancer of the Uterus.* *J. Am. M. Ass.* 1944, 65: 877.

A group of presumably well women between thirty and eighty years of age volunteered to come for pelvic examination twice a year for five years to test the value of periodic pelvic examination in the control of cancer of the uterus. A total of 9,111 examinations have been made. 545 volunteers have completed the five-year period.

In the course of these 9,111 examinations, 4 early cancers of the cervix and 1 early cancer of the uterus were discovered. The patients were adequately treated. They remain well, 3 for six years, for five years, and 1 for fifteen months after treatment.

Also in the course of the 9,111 examinations, 461 inflammatory lesions of the cervix were discovered. Two hundred of these have been treated and eliminated.

GROVER BUNNEX, M.D.

Ingraham, C. B., Black, W. C., and Rutledge, E. K.: *The Relationship of Granulosa-Cell Tumors of the Ovary to Endometrial Carcinoma.* *Am. J. Obst.* 1944, 48: 766.

Granulosa and theca-cell tumors may be associated with such excessive and abnormal endometrial hyperplasia that a histological pattern indistinguishable from adenocarcinoma results.

In further investigation of this question the authors studied a series of 6 hysterectomy specimens, including the ovaries, in corpus carcinomas, in order to determine whether or not hyperplasia of ovarian stroma, interstitial cells, or follicular lining cells was associated with carcinoma. This study

showed no constant relationship, and it was found that the ovaries were either partially or completely atrophic in all instances. The amount of deeply basophilic mesodermal tissue present in the ovarian stroma and not demonstrably connected with follicular structures was variable, and while a considerable amount of this tissue was present in some cases, there was almost a total lack of it in others. A further series of 15 corpus cancers was studied for histological comparison with endometrial hyperplasia associated with granulosa-cell tumors.

Examination of such specimens provided an opportunity for comparison of the growth characteristics of corpus carcinoma and the condition of excessive proliferation caused by granulosa-cell tumor.

The most important features of corpus carcinoma are its progressive growth with continuous and irreversible proliferation with invasion of the myometrium and establishment of metastases. Some of these features are lacking in many true carcinomas and in all reported cases of excessive hyperplasia, including the authors.

Two additional cases of granulosa-cell tumor and 1 case of theca-cell tumor of the ovary associated with adenocarcinoma of the corpus uteri are reported.

EDWARD L. CORRELL, M.D.

Peralta Ramos, A. G., and Gramajo, G.: *Immediate and Late Results of the Wertheim-Schauta Operation (Resultados Inmediatos y Alejados de la Operación de Wertheim Schauta).* *Obst. ginec. Mex.* 1944, 3: 766.

Genital prolapse is frequently accompanied by retrodeviation of the uterus. The operation for the correction of these conditions was formerly performed in two stages, a vaginal and an abdominal one. However, it has been found advantageous to suppress the abdominal stage and operate entirely through the vagina. The Wertheim-Schauta operation fulfills this requirement. It interposes the uterus between the bladder and the anterior wall of the vagina, which occludes the vagina and permits the uterus to act as a support for the bladder. The chief indication for the operation is found in cases of prolapse of the second degree with a large cystocele and incontinence of urine. It is a simple operation and easily accomplished under local anesthesia. The vaginal flora should be studied in determining its indications, and it should be supplemented by the local intraperitoneal use of a sulfonamide. It should be used only for women at or near the menopause as pregnancy under the anatomical conditions created by it is dangerous.

The authors give the histories of 38 patients on whom they have used this operation. Fourteen of them returned for later examination and of these 11 or 78.5 per cent, were permanently cured, while 3 or 21.43 per cent had a recurrence. It is a good

operation for genital prolapse provided it is performed on the proper indications. North American physicians call this Watkins operation as they claim that the first interposition operation was performed by Watkins in 1898.

Recurrences are generally caused by elongation of the cervix, and to prevent them Wagner recommends amputation of the cervix during the operation and Wertheim proposes fixing it to the uterine ligaments.

AUDREY G. MORRAN, M.D.

ADnexAL AND PERIUTERINE CONDITIONS

Rabin, I. C. Novak, J. and Squire, J. J.: Ovarian Fibromas and Theca-Cell Tumors. Report of 78 Cases, with Special Reference to the Production of Ascites and Hydrothorax (Meigs Syndrome). *Am. J. Obst.*, 1944, 48: 601.

The first group of tumors reported from 1928 to 1936, consists of 23 cases. In 7 the tumors were small, measuring at most 5 cm. in 10 cases they were of medium size, from hen-egg to apple size and in 5 cases they were large, bigger than an average sized grapefruit. In 1 case there was no definite note as to size. Ascites was observed in 9 cases of this group. In 2 cases the amount of fluid was small, in 3 moderate, and in 4 considerable. In 6 cases with ascites, the tumors were of large size and in 3 they were of medium size. In 7 cases, the tumors were edematous and for the most part, cystic in 2 cases they were hemorrhagic. Hydrothorax was found in only 1 case of the group. The pleural effusion was bilateral and much more pronounced on the right side than on the left. It was hemorrhagic, whereas the ascitic effusion was described as amber colored. This unusual circumstance is not explained by the authors.

The second group of tumors consisted of 30 fibromas (including fibromyomas), 2 papillary fibroadenomas, and 23 theca-cell tumors. This fairly large group indicates incidentally that theca-cell tumors are not as rare as has been generally assumed. Three of the fibromas were large, 14 of medium size and 13 small. There was a small amount of ascites in only 2 of the fibroma cases. The relative infrequent occurrence of ascites in this group is difficult to explain. In 1 of the 2 cases of papillary fibroadenoma a small amount of ascitic fluid was found at operation. Hydrothorax was not found in any of these 30 cases of ovarian fibroma.

Among the 23 cases of theca-cell tumors, ascites was noted 7 times. The abdominal effusion was extensive in 3 cases with large tumors. A hydrothorax on the right side was associated with the ascites in 1 case. In 4 cases with a moderate amount of ascitic fluid, the tumors were only of medium size, i.e., from that of a hen's egg to that of a grapefruit. In 6 cases with ascites, the new growths were edematous, and in 4 cases cystic.

Ascites is not a frequent occurrence in ovarian fibromas if one considers all of the fibromas including the small ones.

Ascites as well as the combination of ascites and hydrothorax (Meigs syndrome) is also found in theca-cell tumors.

The ascitic fluid probably originates from the tumor itself. Gelber's observation on the oozing of fluid from an ovarian fibroma placed in a dry vessel should be verified. The conditions which may bring about a lymph congestion in the tumor should be studied by a thorough examination of the lymph and blood vessels in the tumor tissue in the pedicle and on its surface.

In every case of Meigs syndrome the specific gravity, the albumin and cell content and the osmotic pressure of the ascitic and pleural effusions should be determined.

The anatomic routes by which fluid is transferred from the peritoneal into the pleural cavity are described. Living cells, cell debris or chronic inflammatory changes of the peritoneum or of the pleura may block the connections between these two cavities.

The prevalence of pleural effusions on the right side can be explained by anatomic and physiological conditions, i.e., the better development of the diaphragmatic lymph channels, the higher position of the diaphragmatic dome and the more intensive pumping action of the diaphragm on the right side.

A hydrothorax can best come about not only if the ascitic fluid is poor in colloids, and therefore can easily pass the diaphragm, but also if the absorption and deportation of the fluid is not rapid enough in the pleura to prevent its accumulation.

MISCELLANEOUS

Miller, H. E.: Deaths in Gynecology. *Am. J. Obst.* 1944, 48: 834.

The general impression received from a study of 401 deaths (two-thirds of which were due to malignancy) is that, on the whole, the cases were well managed from the standpoint of the hospital and that in the great majority of cases (particularly the malignancies) after due allowance is made for the speed and general hopelessness of such conditions as adenocarcinoma of the ovary the patients were responsible for their own deaths. On the other hand in perhaps 25 per cent of the cases with death from malignant disease the patients might have been given a chance of life and in perhaps half with death from benign disease the outcome might have been different if the plan of management outside as well as inside of the hospital had been different in some or in all respects.

Ectopic pregnancy was the cause of the death of 15 patients, 9 of whom were not submitted to surgery. This is a truly startling situation for of all emergency gynecological conditions, none responds more promptly and more satisfactorily to surgical therapy than ectopic pregnancy. Histories should be taken with much more care from every standpoint.

There should be less complacency about the risk in both uterine fibroids and pelvic inflammations. In this series, the responsibility for the cases in which there was an unwise estimation of the risk was about equally divided between the surgeon and the medical consultant.

In all surgical cases there could well be a more careful evaluation of the need for preoperative therapy even when the patients seem fair risks and present only minimal deviations from the normal. Blood surveys should be carried out in all cases, and mild degrees of anemia, hypoproteinemia, urinary tract disease, and hepatic dysfunction should be investigated.

There should be more alertness after operation to detect possible complications in their incipency more speed in instituting treatment when such complications are discovered, and a quicker resort to such measures as intestinal decompression, infusion transfusion, and oxygen therapy when it is evident that less active measures are not achieving results.

More discretion should be employed in discharging patients in certain categories without adequate provision to bring them back if they do not return voluntarily as directed. A fair number of women with malignant disease in this series signed their own death warrants because, when they improved after irradiation which was well begun, they failed to return for more. Patients with pelvic inflammations who responded to bed rest often delayed likewise.

Patients with obvious abscesses, among whom the proportion of rupture was startlingly high, should be kept under observation in the hospital and should be

operated on promptly when maximum improvement is evident, or when it is clear that no further improvement can be expected.

A more general use of total hysterectomy would automatically prevent the development of a certain proportion of cases of malignancy of the cervix.

It should never be forgotten that a patient with one disease even if that disease is malignant, may have or develop another disease even a malignant one at the same time. Pelvic examination should be made a routine part of all physical examinations. A much higher "index of suspicion" of malignant disease, and especially of malignancy of the cervix, must be ingrained in medical students, interns, and residents. Interns and residents, in particular must be imbued with the belief that not all instances of malignant disease are hopeless, an idea which a surprising number of them now seem to possess, and which results in an eager desire to clear the wards of such cases and to use the beds for other purposes. For frank errors of diagnosis and treatment we are responsible as individuals, and most of the preventable deaths from benign disease in this series fall into that classification.

As many of these cases show the menopausal years are a period of particular danger in a woman's life because of the possible confusion between the expected irregularities of those years and the early symptoms of malignancy of the cervix. The solution would seem to lie in teaching women to submit to pelvic examination at regular intervals whether or not they present symptoms.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Ayre, J. E., and Kearna, P. J.: The Course of Pregnancy Following Total Ovarian Ablation
Canad. M. Ass. J. 1945 52 24.

The authors report a case of removal of an ovarian cyst in a patient two and one-half months pregnant whose other ovary had been previously removed. Following the operation from the sixty third to the eighty third day of pregnancy the urine pregnandiol readings were zero consistently but they later increased to a high of 189. The pregnancy advanced normally until about five months at which time it terminated spontaneously.

The period during which no pregnandiol was excreted probably represents the interval between the removal of the corpus luteum and the assumption of the function of hormone production by the placenta.

J. ROBERT WILLIAMS, M.D.

Williams, P. F. and Corbit, J. D.: An Analysis of 161 Fatalities from Ectopic Pregnancy
Am. J. Obst., 1944, 48 841

In Philadelphia, among 2204 ectopic gestations recorded by the hospital record librarians and the Coroner's office from 1931 to 1943 inclusive there were 101 deaths, a mortality of 4.6 per cent.

This study presents a review of these fatalities and attempts to fix responsibility for the deaths, and to seek out the avoidable factors.

The responsibility has been found to be divided between the patient and her family, the referring physician and the attending surgeon and his hospital staff. The avoidable factors have been found to include lack of education of the lady regarding early and adequate prenatal care, failure of the referring physician in recognizing the possibilities of differential diagnosis, failure on the part of the surgeon in diagnosis and because of delay in operating, lack of transfusion, and poor choice of operative procedure.

EDWARD L. CORKILL, M.D.

Crabtree, E. G.: The Use of the Sulfonamides in Pylonephritis in Pregnancy
J. Am. M. Ass. 1944, 126 810

According to the author sulfonamides have greatly modified the management of pylonephritis in pregnancy. There is a definitely good effect which will make itself apparent promptly as a rule. Patients who show signs and symptoms of pylonephritis in pregnancy were given 2 gm. daily of sulfathiazole or sulfadiazine for six days. Sixty grains of sodium bicarbonate are also given three times daily while the patients are receiving the sulfa drugs. The fluid intake is between 2500 and 3000 cc. of water daily in addition to other fluids in the diet. This routine is followed with outpatients. Whenever patients are febrile they are hospitalized and the routine is more

varied. Alkalinization, forcing of fluids, and sulfathiazole are the basic items in the treatment of these patients.

All patients treated are relieved of symptoms although the patients are not all cured.

All obstetrical patients with pylonephritis should be given a course of sulfonamide therapy and if the infection is not cleared up by this they should be investigated for lesions of the urinary tract.

Cystoscopy is used more for diagnosis than for its therapeutic effect. Many patients are discharged from the hospital with infected urine and no symptoms. This may cause preventable gross damage to the urinary tract after long or repeated injuries. Therefore, it is important to realize that subsidence of symptoms following sulfonamide therapy does not mean cure. Patients should be checked carefully after pylonephritis is diagnosed and followed up for some time thereafter.

HARRY FIELDS, M.D.

Flinn W. F.: Lymphogranuloma Venereum in Pregnancy
Am. J. Obst. 1944, 48 696

The author briefly reviews 11 cases of lymphogranuloma venereum in pregnancy from the New York Lying In Hospital. Patients with this disease are usually colored and they are almost invariably syphilitic therefore when one encounters such a patient with a rare venereal disease one can almost infer that she will have a more common venereal disease. These patients are frequently anemic.

As to the type of delivery a vaginal examination before the onset of labor or in early labor will give the most information. If there is marked perineal fibrosis, soft tissue masses or fixation of the posterior vaginal wall, vaginal delivery will be fraught with difficulty and danger.

It is interesting to note that in both of the cases of rupture of the rectum, breech extraction was performed. Hence, when a breech presentation is found in a woman with a stricture of the rectum external cephalic version should be attempted.

One colored patient (a para iv and gravida vi), after a three-hour first stage and a one hour second stage of labor, developed a semicircular rupture of the uterus. She was operated upon and recovered. She also had syphilis. EDWARD L. CORKILL, M.D.

LABOR AND ITS COMPLICATIONS

Morgan, J.: Report on 130 Consecutive Cases of Placenta Previa without Maternal Death
J. Obst. Gyn. Brit. Empire 1944, 51 509.

The author reports a consecutive series of 130 cases of placenta previa without a maternal mortality and with a fetal mortality of 22 per cent.

Of the 130 placentas 32 were implanted centrally, 46 were marginal and 52 were lateral. Treatment was as follows:

INTERNATIONAL ABSTRACT OF SURGERY

361

- Central placenta previa (32 cases)
 - Cesarean section
 - Application of Willett's forceps
 - Manual removal of the placenta before delivery of the infant when the patient was admitted fully dilated
- Marginal placenta previa (46 cases)
 - Cesarean section
 - Application of Willett's forceps
 - Pulling with the half-breach
 - Artificial rupture of the membranes
 - Normal delivery
- Normal placenta previa (52 cases)
 - Cesarean section
 - Application of Willett's forceps
 - Artificial rupture of the membranes
 - Normal delivery
- Other deliveries were required in 16 cases. The causes of fetal death were:
 - Prematurity
 - Congenital atelectasis
 - Cerebral hemorrhage
 - Congenital defects

- Dempsey, E. W., and Wietlocki, G. B.: Observations on Some Histochemical Reactions in the Human Placenta, with Special Reference to the Significance of the Lipoids, Glycogen, and Iron. *Endocrinology* 944, 35 409.

The authors describe some interesting histochemical reactions in the placenta. These are concerned chiefly with lipoids, glycogen, and iron. The material for study consisted of 9 human placentas of various ages, the youngest coming from an embryo 3 mm. length. Some of the placentas were fixed in various reagents for special cytological study while others were studied fresh and unfixed.

The types of study included fluorescence studies, transillumination with ultraviolet rays, and birefringence with a polarizing microscope. The Schiff, or "plasmal," reaction of Penzance and Voit was used to study aldehydyl compounds, and strong sulfuric acid was applied to fresh and formalin fixed tissues to determine the localization of sterol-like substances. Best's carmalum stain was utilized to locate glycogen. The oxidative systems of the placenta were studied by means of the application of "nadi" reagents and their ability to oxidize or reduce a series of indicator dyes.

The conclusions reached by these observers are that lipoids of the fetal placenta occur almost entirely as droplets in the syncytial trophoblast. These droplets contain steroidal substances. The cytotrophoblastic cell columns, cell islands and cytotrophoblastic shell contain glycogen, especially during the early part of pregnancy. Similarly, a considerable amount of glycogen is present in the decidua in the first half of pregnancy. The authors suggest from their conclusions that glycogen deposition is

associated with anaerobic conditions, and that through anaerobic breakdown a mechanism for oxidative reactions of tissues in which the oxygen supply is deficient is produced. They also concluded that the syncytium of early placentas contained a considerable amount of iron, while in the later stages of pregnancy this amount is greatly reduced. These findings are interesting with regard to iron transport by the placenta.

HARRY FRANKS, M.D.

- Aravena, O.: Maternal Mortality from Obstetrical Causes in Chile (Sobre mortalidad materna por causas obstetricas en Chile). *Bolet. Soc. chilena obst. ginec.* 1944, 9 179.

The author gives tables which show the maternal mortality from obstetrical causes in Chile from 1919 to 1943. The causes of death are also tabulated and the statistics are compared with those of other countries. Part of the statistics were obtained from the Government Statistical Bureau and part from various hospitals, and attention is called to the differences for the differences in the government and hospital statistics. The author believes that the best way of calculating such statistics is to count the number of maternal deaths to every 10,000 infants born alive. The arguments for and against the various methods of computing statistics are set forth.

The author finds with regret that there has not been a decrease in the maternal mortality in Chile within this period comparable with that in other highly civilized countries. In the United States there has been a rapid decrease in maternal mortality since 1930. In England and Wales there has been some improvement in the last decade while in Norway and the other Scandinavian countries the figure is very low.

He attempts to explain the backwardness of Chile in this respect. Chilean physicians know the most modern medical and surgical methods of management of delivery and the puerperium. However, the infant seems to be in the fact that the mass of the population is not made available to a medical question. It is a social as well as a medical society devoted to the investigation of the causes of maternal mortality and a detailed study of each case of death, while in Chile there is no such activity. Chile should organize early and compulsory prenatal control, and pregnant women should be under medical observation and care from the beginning of pregnancy. Medical and scientific societies should accept the responsibility of bringing about better obstetrical care for the mass of the population.

In the discussion the facts were brought out that it is difficult to lower the maternal mortality until induced abortion with its high percentage of sepsis can be controlled and also that the highest mortality in Chile is in the country districts where the skilled medical care of the cities is not available.

ARMANDO G. MORALES, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Dermady E. M. Siddons, A. H. M., Corson, T. C. Langton, C. D. and Others: Traumatic Uremia; Reports on 8 Cases. *Lancet*, Lond., 1944, 247 809.

Six fatal cases and 3 nonfatal cases of uremia which occurred in young soldiers a few days following injury by high-explosive missiles are reported. The injuries were severe but in themselves did not seem sufficient to cause death. All of the men developed oliguria, vomiting and a raised blood urea. Many of them had a low blood pressure and were in clinical shock at one time during their illness. Pathological examination of the kidneys in 4 cases coming to autopsy revealed enlargement of the kidneys with histological evidence of tubular degeneration, interstitial edema, and rupture of the tubules into the venous spaces.

The similarity between the pathology of this syndrome and the crush syndrome is great. The renal changes are probably due to anoxia secondary to hypotension or vascular spasm or both, and are probably not due to 'nephrotoxic' substances liberated from crushed tissues as there was little crushing present in these cases. These 6 fatalities represent one-third of the deaths in a group of 2,000 casualties which were observed in a transit air evacuation hospital in northern France.

WILLIAM W SCOTT M.D.

Dean, A. L., and Abels, J. C.: Study by Newer Renal Function Tests in an Unusual Case of Hypertension following Irradiation of One Kidney and Relief of the Patient by Nephrectomy. *J Urol*, Balt., 1944, 52 497.

The measurements of renal function commonly employed by urologists such as the determination of blood nonprotein nitrogen and urinary concentration and the dilution tests, do not always measure accurately the amount or nature of renal damage and provide still less information of the reserve capacity of the organs.

A case illustrative of the value of the newer renal function tests is presented. At the age of twenty years a woman complained of an abdominal mass of six weeks duration. Except for the mass, physical and laboratory examinations were normal. Urograms were normal. Under a diagnosis of lymphosarcoma or Hodgkin's disease 3,000 roentgens were administered through anterior and posterior portals, and it was calculated that the kidney received 4,600 roentgens. The tumor disappeared completely but seven years later the patient's blood pressure was 150/100, and when headaches began to appear it was found to be 184/125. Excretory urograms showed a shrunken left kidney with diminished function. The usual tests showed little impairment of

the left renal function but when the rate of glomerular filtration was measured by the mannitol clearance technique it was found that the left kidney cleared only 17 ml./min. The renal blood flow as determined by the sodium para-aminohippurate method was 410 ml./min. for the right and only 70 ml./min. for the left kidney. Maximum tubular secretion of this compound was shown to be 50 mgm./min. on the right side and 6 mgm./min. on the left side.

Following removal of an atrophied left kidney the blood pressure fell from 160-172/120-130 to 112-120/72-80 within one week. During the following fourteen months the blood pressure remained in this range and renal function tests showed slight improvement in the function of the remaining kidney. Vascular responses to cold and nitroglycerin which were poor preoperatively became normal and the venous pressure and circulation times decreased to normal values following operation.

It is suggested that when it is important to determine the functional capacity of a kidney use of the newer tests of renal function be made as the present function tests are frequently inaccurate and are not sufficiently sensitive to detect renal damage.

WILLIAM W SCOTT M.D.

Deming, C. L.: Acute and Chronic Symptoms and the Diagnosis of Movable Kidney. *Pennsylvania M J*, 1944 48 207.

Although mobility of the kidneys is normal, in some adult females it causes pain presumably because of temporary obstruction of the pelvis of the kidney. Pain, the most common symptom of pathologically movable kidneys, is usually referred to the corresponding costovertebral angle although gastrointestinal complaints and nervous symptoms may predominate. In a certain proportion of the cases hydronephrosis is present and impaired renal function and delayed emptying of the renal pelvis are the late effects of pathologically movable kidneys. Treatment of 200 selected cases by suspension of the kidney resulted in failure to relieve the symptoms in only 4 cases.

The author mentions the fact that the Kelly stitch operation and capsule-stripping operations for nephropexy should be avoided because of the danger of perinephritis and hypertension. The author's nephropexy consists of complete mobilization of the kidney pelvis, and ureter, the kidney being placed in its correct position and the anterior and posterior layers of the perinephric fascia being approximated with chromic mattress sutures to maintain the kidney in normal position. Nephropexy may be indicated following pyelolithotomy or plastic operations on the renal pelvis to maintain the normal position and emptying of the pelvis of the kidney.

DONALD F McDONALD, M.D.

Crabtree E. G.: Leiomyoma of the Kidney Associated with Hemorrhagic Cyst. *J Urol*, Balt., 1944, 5: 450.

Tumors which arise from smooth muscle tissue and are situated beneath the true capsule of the kidney are usually small, multiple, benign fibromyomas and usually do not require surgical treatment. Myomas of the kidney have grown to larger size, produced symptoms, and assumed surgical significance in a very small number of reported cases. Of 8 reported cases of renal myomas of large size only 3 were histologically malignant. The benign myomas have a tendency toward cyst formation both in association with the tumor and within it. Of the 6 reported benign myomas 3 were accompanied by cyst formation, whereas the 3 malignant myomas lacked cysts. In the cyst wall, encrustation with cholesterol or calcium was the rule. Both benign and malignant tumors have been found well encapsulated within the renal capsule. Results of nephrectomy for renal myoma are good no doubt because extension into the perirenal fat and veins does not occur. Of the 8 tumors recorded 6 have been in women. The age incidence of renal myoma is from twenty-one to fifty-two years with 7 patients under thirty-nine years.

Two cases of renal myoma are presented. One was benign and occurred in a male aged thirty-nine years whose initial complaint was loin pain and who has remained well for six months. The other was malignant and occurred in a forty-three-year-old woman who complained of a left abdominal mass. Following nephrectomy it recurred in three years and was again removed then it recurred in two years at which time further surgery was instituted.

In the first case the tumor was a thick-walled cyst 5 cm. in diameter the wall of which contained calcification and whorls of smooth muscle and connective tissue without evidence of malignancy. In the second case the tumor was 16.5 cm. in diameter and was not cystic. Microscopic examination showed connective tissue, smooth-muscle cells, and numerous mitoses which led to the diagnosis of leiomyosarcoma.

Until greater familiarity with the clinical appearance of leiomyomas of the kidney is attained pathological examination of the specimen removed by nephrectomy should be regarded as the only reliable method of establishing the malignancy or benignancy of the tumor.

WILLIAM W. SCOTT, M.D.

Sugarbaker E. D.: An Application of Staging in the Removal of Difficult Wilms Tumors. *Ann. Surg.* 944, 30: 90.

Mixed tumors of the kidney occur most frequently in infancy and early childhood. They are characterized by rapid growth to large size and early metastases to the lung and liver and have a quickly fatal termination.

Roentgenotherapy either alone or as a preoperative adjunct is much inferior to immediate nephrec-

tomy. A transperitoneal approach is desirable because it permits of the intact removal of the tumor and the perinephric fat within the fascia of Gerota. Another advantage of this approach is that it permits primary ligation of the renal pedicle before the tumor is disturbed, which is desirable because of demonstrable renal vein involvement in 45 per cent of the cases.

Operability of these tumors depends not only upon the presence of metastases but also upon the technical ability of the operator and the size and position of the tumor. Operability may be extended by dividing the operation into two stages to minimize the risk and to facilitate the excision of the bulky very vascular tumor. Ligation of the pedicle of the kidney and mobilization of a portion of the tumor at the first stage permits of rapid excision with less bleeding at the second stage. The kidney and tumor should be removed intact with the perinephric fascia and fat and the overlying peritoneum.

A case of mixed tumor of the right kidney in a twelve-year-old boy in which a 1,760 gm. specimen was removed by the two-stage procedure described is presented in detail. The stages were six days apart, and the patient is in good condition two years after operation without evidence of recurrence.

DONALD F. McDONALD, M.D.

McClelland, J. C.: Primary Carcinoma of the Ureter Treated by Excision and Anastomosis of the Cut Ends. *J Urol*, Balt., 1944, 51: 5.

A man, aged sixty-two, noticed two weeks before consultation that there was some blood in the urine after walking. The blood was intimately mixed with the urine, and he noticed a few small clots. There was no frequency, no pain, and no difficulty in urination. He gave a history of having passed 3 stones from his left ureter two years ago. There was an indefinite area of pain in the left lower quadrant, but none in the right lower quadrant.

Under local anesthesia a No. 24 F. cystoscope was introduced and clear urine was found in the bladder. The vesical mucosa throughout was pale pink in color and showed no stone, tumor, or foreign body. No intravascular enlargement of the prostate was present. The ureteral orifices were examined and no efflux was seen coming from either side. A catheter passed up the left ureter did not meet any obstruction. The right ureter was not catheterized as the patient had had his pain on the left side previously and the author suspected a recurrence of ureteral stone. The left pyelogram was negative for calculus or any abnormality in the pelvis or ureter.

An intravenous pyelogram showed a right hydronephrosis with a kinking of the upper ureter. The cystoscopic examination was repeated and a stricture in the lower end of the right ureter, a kink at its upper end, and an incompletely filled hydronephrosis were found. A tentative diagnosis of new growth in the lower end of the right ureter was made and an exploration recommended.

Fig. 1. Diagrammatic representation of ureter in section, showing growth and its lumen. Lincs show areas where ureter was cut off. 2 Stay sutures draw cut ends and ureter together and slit was made above to insert T tube.

Fig. 3 and 4. Cut ends of ureter being approximated around T-tube with lower arm of T tube extending into the lower ureter. Continuous suture of No. 0000 catgut was used after stay sutures were tied.

An incision 10 inches in length was made in the lower right quadrant of the abdomen lateral to the rectus muscles, with the anterior superior spine in the middle of it, but 2 inches medial to it. The external oblique muscle was split in the direction of its fibers, while the internal oblique and transversalis muscles were cut and the ureter was exposed by pushing the peritoneum toward the midline. Just below the brim of the true pelvis the ureter showed a hard area which was discrete and not attached to any surrounding structures. The ureter immediately above the lump was quite dilated while the ureter below was not enlarged but the usual size. No evidence of any secondary tumors was seen. It was believed that this was a new growth, primary in the ureter and the decision was made to excise it and join the 2 ends. The ureter was freed well up to and including the kink and plenty of slack ureter was present. Figure 1 (1) shows where the ureter was cut across in relationship to the growth. The upper portion was cut straight across and the lower portion cut on a slant. This was done in order to make the lower small ureter approximate more closely the size of the upper ureter. Figure 1 (2)—A slit was made in the upper portion and a stay suture introduced to hold the edges together. In Figure 3 the small T tube has been inserted and the lower end carried into the lower ureter. Several stay sutures were inserted after which a continuous suture was placed around the area of the anastomosis. When this portion of the operation was finished, it was believed that this should give a water tight joint. No tension was present, but the ureter was quite slack. No 0000 plain catgut was used to suture the

ureter. The wound was closed in layers a small tube being left down to the site of the anastomosis.

The wound was quite dry until the sixteenth day when urine began to come around the tube and the patient had a low fever. This continued until his twenty first day when the T tube was withdrawn. The wound was wet a few hours only and completely dry in twenty four hours and did not leak again.

The urine in the meantime had begun to show a good deal of pus. The prostatic secretion also contained a good deal of pus. A few prostatic massages and mandelic acid cleared the urine, the temperature came down and the patient's condition was much improved.

Twenty six days after the operation an attempt was made to catheterize the right ureter. Various catheters were used these were blocked immediately at the ureteral orifice and did not reach the site of the anastomosis. It was decided that edema was causing the obstruction and an attempt should be made at a later date to dilate the ureter.

Three and one half months after the operation under spinal anesthesia the McCarthy panendoscope was used, and a large No. 12 bougie passed up the right ureter. This was obstructed at 5 cm. but went through with a little difficulty. It was withdrawn and a No. 11 Garceau catheter was passed. Good dilatation was obtained. Six weeks later dilatation was repeated under local anesthesia. Some slight obstruction was present but the ureter was dilated easily.

The pathological report was papillary carcinoma

Roberts, M: An Analysis of 90 Cases of Transplantation of the Ureters for Obstetric Vesicovaginal Fistula. *J. Obst. Gyn. Brit. Empire*, 1944, 51: 519.

A series of 90 patients with obstetric vesicovaginal fistula treated by transplantation of the ureters into the colon is presented. Various techniques were used, and the operative results are tabulated. The mortality with each technique may be seen from the following table

TABLE I—RESULTS OF 2 DIFFERENT METHODS (OMITTING 2 ANESTHETIC DEATHS)

Type of Operation	Cases	Deaths	Mortality per cent
A. Winsbury-White	9	3	5.8
B. Coffey No. 1—two-stage	41	—	3.4
C. Coffey No. 2—two-stage	7	5	30.7
D. Coffey No. 3—two-stage	3	—	—
E. Coffey No. 4—two-stage	5	—	50.0
F. Mixed, in two stages	4	1	5.0
G. Mixed in one stage	3	—	—
Average mortality 12.			
All types in one stage	24	6	5.0
All types in two stages	66	5	7.8

The author does not compare these techniques with repair of the fistulas, nor does he evaluate the more remote results. JAMES F. DONNELLY, M.D.

BLADDER, URETHRA, AND PENIS

Bellie, C. J.: Cystostomy after Spinal Anesthesia. *Surgery* 1944, 16: 896.

Ninety-four men without urological diseases and with ages ranging from eighteen to thirty five were operated on under spinal anesthesia, and cystostomies were made as soon as sensation below the level of anesthesia returned. The procedure followed in this investigation was detailed and an illustration thereof was published in the article.

Controlled determinations were made on 5 persons who had been given intravenous sodium-pentothal anesthesia for very short operations. The results showed that in the spinal-anesthesia group the intra-vesical tension increased slowly as the bladder was distended with fluid. The strong rhythmic contractions indicated by fluctuations in the manometer column coincident with the desire to void, occurred at greater volumes and at higher pressures than in the controls.

Since the stretch reflex for the bladder is in the sacral cord, it is not surprising that residual vesical effects are found after the use of spinal anesthesia.

A discussion of the results obtained included the anatomy of the nervous supply to the bladder in relation to micturition. Spinal anesthesia is considered to establish temporarily a type of neurogenic vesical dysfunction probably due to the anesthetic agent. The bladder wall remains somewhat insensitive to its distending contents, and although the expulsive force of the detrusor muscle may actually not be diminished, the normal strong reflex vesical

contractions which coincide with the desire to void do not appear until the volume of the bladder and intravesical tension are so great as to invite further pressure anesthesia of the wall and a continued sensory type of retention which initiates urinary infection.

An early catheterization by preventing pressure anesthesia of the bladder wall, will facilitate early subsequent spontaneous voiding while delayed and widely spaced catheterization serves to aggravate the neurogenic dysfunction and precipitate infection.

MARY KARP, M.D.

Emmett, J. L., and Cristol, D. S.: Urinary Retention Following Surgical Operation on the Rectum and Sigmoid. *J. Am. Med. Ass.*, 1944, 36: 1077.

Urinary retention in the male patient after operations on the rectum and sigmoid is not as complex as has been heretofore supposed. Reduced to its basic components it may be stated simply. Most patients subjected to this type of operation are in the age of prostatic. It has been recognized for years that many factors such as chilling, alcoholic or sexual excess overeating or surgical operations on other parts of the body will precipitate urinary retention in such cases. Trauma to the prostate and urethra plus the removal of the supporting structures around the base of the bladder (such as occurs after posterior resection or combined abdominoperineal resection) furnishes an ideal situation for the bladder to decompensate and become unable to expel urine through a moderately obstructed vesical neck.

Instead of an attempt to increase the vesical tone (which is impossible by any means available at present) the rational procedure is to weaken the vesical neck and obviate the imbalance that exists between the detrusor muscle and the vesical neck. This can be easily accomplished by transurethral prostatic resection and will completely and quickly relieve nearly all patients suffering from this annoying condition. To avoid an unnecessary operation it is probably best to allow the patient a period of at least three weeks after the intestinal operation to regain his vesical function before transurethral resection is advised.

Berry, H. C.: Traumatic Rupture of the Urethra and Bladder. *Austral. N. Zealand J. Surg.* 1944, 14: 104.

Rupture of the lower portion of the urinary tract, although relatively rare, is, nonetheless, important because early adequate treatment may avert a serious or undesirable outcome. Traumatic lesions of the lower urinary tract may be classified into three main groups: namely, (1) ruptures of the anterior urethra, complete or incomplete; (2) rupture of the posterior urethra, complete or incomplete; and (3) rupture of the bladder extraperitoneal or intraperitoneal. The anterior urethra is ruptured by direct violence, and usually it is the bulb which is crushed against the pubic arch. The lesion is often diffuse and the periurethral tissues are pulped. Rupture of

the posterior urethra is associated with a fractured pelvis and is caused by indirect violence. The lesion is more circumscribed, but there is often wide separation. Traumatic rupture of the bladder is usually a complication of a fractured pelvis but it may follow direct trauma to a distended bladder. Although penetrating injuries due to missiles of war will not fit into this classification, the principles of diagnosis and treatment are similar.

Rupture of the anterior urethra commonly follows a fall astride or a blow to the perineum in the male. The presenting signs are bleeding from the meatus, bruising in the perineum, and retention of urine. Shock is seldom severe. Catheterization is unnecessary for diagnosis. In typical cases the spasm of the sphincter prevents extravasation of urine for several hours. Unless the injury is at the distal end of the penis and the patient is able to void satisfactorily early suprapubic cystostomy is indicated. In many cases this is all that is necessary but when perineal hematoma is present or in late cases with extravasation of urine, perineal drainage must be established. Perineal incision also permits of inspection of the urethra and suture of the divided ends. If the tissues are edematous and the urethra cannot be united without tension, only the roof of the urethra should be sutured. Early suture is not essential provided diversion of the urine is adequate. Suprapubic drainage must be maintained until the perineum is healed and any stricture is fully dilated. An indwelling urethral catheter except when the edema has subsided and the wound is healing is contraindicated by the danger of infection and increasing stricture formation. Regular dilatation of the urethra following healing of the wound must be carried out in some cases for a few months, and in others for life. Complications depend on the residual urethral stricture and its sequelae perineal abscess, urinary fistulas, urinary infection and calculus formation, chordee, sterility and impotence.

Rupture of the lower urinary tract occurs as a complication of a fractured pelvis in probably less than 5 per cent of cases. It depends upon the site of fracture and the degree of displacement of fragments. Rupture of the lower urinary tract must always be suspected when separation of the symphysis or fracture of the pubic ramus is present and especially in cases of complete fracture dislocation of the pelvic girdle. The urethra may be torn where it is held fixed by the membranous sphincter and either the bladder or urethra may be pierced by sharp fragments of bone. When the pelvis is laterally compressed and its anteroposterior diameter increased the puboprostatic ligaments may be torn and as blood and urine accumulate in the prevesical space the bladder and prostate may be rotated upward and backward until there is often a gap of an inch or more between the torn ends of the urethra. In neglected cases the bladder may become anchored in its new position and late attempts at restoration may be fruitless. In these types of rupture the injury is often rapidly fatal or the patient is in such severe

shock that restorative measures must be instituted immediately to preserve life. Reduction of the displaced fragments of the fractured pelvis prevents further shock and hemorrhage and may bring together the torn ends of the urethra. Temporary immobilization of the pelvis by a pelvic sling until operative measures to drain the bladder and restore the urethra are instituted is indicated. Diagnosis of intrapelvic rupture is established by the presence of suprapubic tenderness and dullness, retention of urine, bleeding from the meatus and dislocation of the prostate upward. At this stage intrapelvic rupture of the urethra and extraperitoneal rupture of the bladder can rarely be distinguished. When there is doubt expectant treatment should never be adopted. A catheter must be passed and only if a normal amount of clear bloodless urine is withdrawn can the urethra and bladder be considered intact. When bloody urine is obtained the catheter may lie in the prevesical space or in the peritoneal cavity and suprapubic cystostomy and exploration are indicated. Accessory investigations such as retrograde and excretion cystograms and injection and withdrawal of known quantities of solution are uncertain and unnecessary and they waste time. At the time of suprapubic cystostomy a urethral catheter is passed retrogradely. If it passes into the bladder it is removed a suprapubic catheter is left in the bladder and the prevesical space is drained. When the membranous urethra is completely torn the catheter will pass into the prevesical space. A sound may be introduced into the bladder by manipulation and an indwelling catheter splinting the urethra is withdrawn. If there is a tendency for the displacement of the bladder to persist, traction on a Foley type of catheter may be used to exert a constant pull on the bladder neck. Here also an indwelling splinting catheter is undesirable but the soft parts must be kept in position at all cost. Direct suture of the membranous urethra, although theoretically the most desirable treatment, is attended by an increased risk to an already shocked patient. Late attempts at restoration of inadequately treated ruptured membranous urethras usually are unsuccessful and incontinence is usual.

Rupture of the bladder occurs as a complication of a fractured pelvis or following direct trauma to a distended bladder. About two-thirds of the ruptures are intraperitoneal and the mortality in these cases is about 50 per cent, depending also upon the severity of the concomitant injuries and the time elapsed between rupture and drainage of the bladder. In gunshot wounds, especially of the buttocks, in fractures of the pelvis, or when there has been a blow to the abdomen (especially in an alcoholic) the possibility of rupture of the bladder must be investigated by catheterization. If clear bloodless urine is not obtained the patient must be operated upon immediately. A suprapubic incision having been made an extraperitoneal rupture is obvious by the wide spread extravasation of blood and urine. Cystostomy is performed and the bladder is explored to exclude

any intraperitoneal lesion. If there is doubt the peritoneum may be opened and closed immediately if no free fluid is present. The prevesical space should be drained. If there is no extraperitoneal rupture the peritoneum is opened, the anterior wall of the bladder is opened extraperitoneally for drainage and the rent in the bladder is repaired. The peritoneal cavity is drained for twenty four hours, the prevesical space a little longer and the cystostomy is maintained for two weeks. In gunshot wounds, injury to other viscera must be excluded. WILLIAM W. SCOTT M.D.

Taylor J. A.: Penile Horn. *J. Urol. Balt.*, 1944, 53, 6.

Cutaneous horn, according to Ewing, is a peculiar form of cutaneous wart marked by excessive and progressive keratosis. These horns may appear anywhere on the skin of the body and are infrequently found on the penis. When found on the penis they are usually on the glans and may be single or multiple.

In view of the fact that these horns grow on a wart or acanthoma and are merely a progression of the keratosis already present in these two conditions, then it would seem that they are the result of prolonged irritation usually from a long prepuce.

Keratosis is a general term applied to pathological epidermoid proliferations, and the importance of keratosis as a precursor of cancer cannot be overestimated.

The author's patient was a thirty-five-year-old German male. His mother and father had both died of cancer. There was no relevant past history. His present illness began in Germany three years before when he noticed a small wart on the left aspect of his glans penis. The prepuce was adherent to the glans so a circumcision was performed, and the wart was excised. It recurred promptly and grew until it was again removed in March, 1939 in this country. On admission it had recurred and the patient presented a warty growth 1 cm. in diameter on the distal lateral aspect of the glans penis. General physical examination was essentially negative.

Fig. Firm, hornlike growth from the penis.

Under low spinal anesthesia, the warty growth was excised with the electrosurgical knife. The pathological report read as follows: Macroscopically the specimen consists of a wedge-shaped piece of tissue 12 mm. long which has the appearance of a verruca. Microscopically, sections through the tissue show the growth to be composed of broad papillary masses of squamous epithelium with a few pearls but consisting largely of prickly cells. The basal layer is hypertrophic, and there are many mitotic figures. The tumor is growing in a papillary manner but with long extension of cells into a very vascular stroma. The type of cells and the manner of growth are more extensive than occurs in a papilloma and the growth should be considered an epithelioma, but being highly differentiated and not showing deep infiltration with single cells, it is a Group I.

The patient was readmitted to the hospital in October 1940 eleven months later with a recurrence of verrucous growths extending to the coronal sulcus. Under low spinal anesthesia the growths were widely excised with the electrosurgical knife. This time examination of the specimen macroscopically showed a tumor of the penis in several portions, the largest 1 1/2 by 8/10 cm. in size.

The patient was readmitted to the hospital in July 1943 saying that several weeks after discharge, a small wart appeared and that one month later a horn began to grow out from this wart. It had grown steadily and at present was slightly over 3 inches in length. Under low spinal anesthesia the horn was removed with the electrosurgical knife, a deep wedge being cut into the glans.

The specimen consisted of a firm hornlike growth from the penis 9 cm. long by 3 by 2 cm. at the base and 1 cm. thick at the rounded tip (Fig. 1). On section the base showed papillary outgrowth from the underlying derma. The line of the base was even and there did not appear to be any outgrowth. There was an additional portion from the base of the growth. On section it showed epithelium from 4 to 7 mm. thick with vertical striation on one surface, and beneath this, a fibrous base. Microscopic sections through the base of the growth showed it to be composed of very long strands of hypertrophic squamous epithelium with many anaplastic changes and pearl formation in the deepest portion.

GENITAL ORGANS

Bumpus, H. C., Jr. Massey B. D., and Nation. E. F.: Experience with Orchiectomy for Carcinoma of the Prostate. *J. Am. Med. Ass.* 1945, 27, 67.

The results obtained with bilateral orchiectomy in 25 patients with carcinoma of the prostate are here reported. All of these persons, with 1 exception, showed decided improvement following the operation. Such improvement included such changes as increased vigor, strength, weight, and appetite, a

sense of well being, cessation of pain, and diminished urinary difficulties.

The majority of these patients, although not all of them, were given diethylstilbestrol in doses ranging from 1 to 3 mgm. daily following orchectomy, and 13 had a transurethral prostatic resection in addition to the castration. The condition of the patient which was not improved remained about the same for six weeks before it began to grow worse; however the patient was still alive thirteen months after the orchectomy the metastases progressing and his health failing. (No case histories are appended.)

In the discussion of the results, all of these cases are divided into three groups: (1) 4 patients operated upon two years ago or more; (2) 11 patients operated upon between one and two years ago; and (3) 10 patients operated upon within the past year. Three of the first group cited are alive and well—1 patient at thirty months after orchectomy. One of the 3 had extensive pulmonary metastases which receded after the operation. The fourth is failing rapidly twenty-nine months after operation. Of the second group, 5 are dead, 4 are well, and 1 had a relapse after twelve months of relief. All of the patients in the third group are free of symptoms which indicate advancing malignancy.

There was considerable variation in the length of time required for softening of the prostate after orchectomy and the administration of diethylstilbestrol. There seemed to be no correlation between the length of the interval and the grade of malignancy.

In concluding the authors stress the fact that since 40 per cent of their patients who have been observed for a year or more following orchectomy have had a recurrence of symptoms it is anticipated that all will eventually have a relapse. It remains therefore, to regulate better our use of orchectomy or of the estrogens. It should be delayed probably until symptoms of an advanced malignant condition are manifest, then either method should be used separately or in succession rather than simultaneously.

The authors desire to call particular attention to a remarkable transformation in the patient's state of mind and personal habits (from a slovenly apathetic habitus, to that of neatness, alertness, and interest in his surroundings) which occurred in a striking manner in one of these individuals, and which was more or less manifested by all the patients, immediately following the operation of bilateral orchectomy. This personality transformation is believed not to have been reported previously in the medical literature.

JOHN W. BRENNAN, M.D.

Emmett, J. L. and Greene, L. F.: Bilateral Orchectomy for Carcinoma of the Prostate Gland. *J. Am. Med. Ass.*, 1945, 127, 63.

The indication for bilateral orchectomy is carcinoma of the prostate with metastasis. Bilateral orchectomy is especially efficacious when the metastatic growths have given rise to symptoms. The

period of relief following orchectomy varies from months to years, but whether any patients will remain permanently relieved seems extremely doubtful. Apparently the large majority of patients have a recurrence of symptoms within a year. Whether or not "prophylactic" orchectomy (done in the early stages of the disease before metastasis has appeared) measurably influences the course of the disease is not yet known. This problem cannot be settled until more time has elapsed and a larger series of cases in which prophylactic orchectomy has been performed has been studied. Until this problem has been definitely settled the present practice of the authors is to advise orchectomy primarily for patients suffering from metastasis for the relief of metastatic symptoms. Results to date suggest that when orchectomy is performed in conjunction with transurethral resection the frequency of recurrent obstructive symptoms requiring subsequent prostatic resection is reduced; furthermore, if such symptoms do appear the time interval between resections is increased.

The authors are also treating a group of patients who do not show evidence of metastasis with estrogens after transurethral resection to see if the course of the disease can be appreciably altered over a substantial period. They are interested to know if preliminary estrogenic therapy in such cases will tend to nullify the palliative effects of castration if the latter should become necessary for the control of symptoms later on.

Neesbit, R. M., Pazzos, R., and Cummings, R. H.: The Treatment of Prostatic Carcinoma by Castration and by the Administration of Estrogenic Hormone. *J. Urol.*, Balt. 1944, 52, 570.

The authors compare the results of castration in a series of 75 cases of prostatic cancer from six months to two years after operation with the results in a parallel series of 50 cases treated by the administration of 1 mgm. of diethylstilbestrol daily over periods of from six to thirty-five months.

In both series the relief of pain and the increase in weight have been striking. Complete relief of pain resulted in 64 per cent of the cases subjected to orchectomy as opposed to 56 per cent of the stilbestrol treated cases. Weight gain was better in the stilbestrol series (78 per cent and 72 per cent respectively). Relief of partial urinary obstruction was greater in the orchectomy cases (86 per cent compared with 65 per cent). This would suggest that regression of the carcinoma was more complete following orchectomy. Following orchectomy 85 per cent of the carcinomas decreased in size and 15 per cent became softer as judged by rectal examination. The comparable results with stilbestrol were decrease in size in 33 per cent and softening in 16 per cent. In no castration case was the lesion observed to enlarge or fail to change in consistency or size, whereas in the stilbestrol series increase in size occurred in 12 per cent and no change was observed in 39 per cent of the cases. Metastases

regressed in 33 per cent of the castration cases, whereas in no case given stilbestrol did the metastases regress. Increase in the number and size of the metastases occurred in 67 per cent of the castrated patients and in only 38 per cent of those receiving estrogen. Deaths in the castration series amounted to 7 per cent, and in the estrogen series, to 8 per cent. Favorable responses occurred in 73 per cent and 80 per cent, respectively and whereas there were no immediate failures in the stilbestrol group 7 per cent of the castrated patients failed to derive any immediate benefit from the operation.

One case is presented in which the serum acid phosphatase failed to increase coincidentally with roentgenographical and clinical progression of the disease. Histopathological examination in this case revealed an abundance of acid phosphatase in the metastases.

The authors conclude that the acid-phosphatase level of the serum is an unreliable index of metastatic carcinogenic activity. In summary they advise that although there is little difference in subjective response to the two forms of treatment, orchectomy results in greater objective regression in the primary tumor and metastases. Neither form of treatment affords prophylaxis against the development of or increase in metastases. Pain in postcastration cases can often be relieved by estrogen administration.

DONALD F. McDONALD, M.D.

Barringer B. S. The Prognosis in Teratoma Testis. *J. Urol.*, Balt., 1944, 51: 578.

The vast amount of clinical and pathological material available to the author for study in the past twenty-eight years at the Memorial Hospital, New York City is the basis for the present report.

The preoperative diagnosis of testis tumor with the exception of those rare choriomas which produce high titers of urinary gonadotropins, is uncertain. The prognosis is not altered by preoperative irradiation of the testis. A review of 69 living patients showed that 80 per cent of the tumors were seminomas and 17 per cent were adenocarcinomas. There was 1 case of spindle-cell sarcoma and 1 of adult cystic teratoma. There were no cases of chorioma.

In the case of a patient with a testicular tumor there is a large chance that he has a seminoma and a slight chance that he has an adenocarcinoma. There is only a remote chance that he has a chorioma or a nonmalignant tumor. Of 55 patients with seminoma, 56 per cent were well for five years or more but of these, 29 per cent had metastases. In the group with adenocarcinoma, 83 per cent were well as long as five years, 40 per cent with metastases. While the testicular seminoma is much more radiosensitive than the adenocarcinoma, surprisingly few patients with metastasizing seminoma survive five years, while a relatively high percentage of patients with metastasizing adenocarcinoma survive more than five years.

The lymphatics of the spermatic cord are rarely invaded by testicular tumor although metastases to

the lymph nodes pass through them. The prognosis is grave if metastases can be demonstrated in the cord, the supraclavicular nodes, the abdomen, the lungs, or the periprostatic lymphatics.

Autopsy material in 37 cases showed regional node involvement as follows: Inguinal, 10.8 per cent; pelvic and iliac, 37.0 per cent; lumbar 54 per cent; celiac, 56.8 per cent; mesenteric, 18.9 per cent; mediastinal, 48.7 per cent; bronchial, 35 per cent; and cervical 35.3 per cent. Metastasis to the inguinal nodes is rare unless the tumor perforates the tunica or capsule of the testis. In many cases the center of the metastatic nodules or nodes were broken down and hemorrhagic, and in 5 cases there was hemoperitoneum. Intracranial metastases occurred in 16.3 per cent of the cases, but examinations of the brain were made in less than half of the cases on which autopsies were made. Pulmonary involvement was present in 78.3 per cent of the cases, and 55 per cent of these had also mediastinal node involvement; the pleura was involved in 37.0 per cent of the cases. In 75.8 per cent of the patients with pulmonary involvement, the liver too was involved. The involvement of the liver being hematogenous, is unrelated to that of the testis. The spleen, diaphragm, pancreas, kidneys, adrenal glands, gastrointestinal tract, and skeleton were less frequently involved. Retroperitoneal involvement was found in 58.8 per cent of the cases, and in 33.5 per cent of these the condition was bilateral.

In conclusion, the author advises concentration on the seminoma and the adenocarcinoma. Irradiation should be bilateral because the condition is bilateral in 78 per cent of the cases. Lung metastasis has a poor prognosis because liver involvement is present in 75 per cent of the cases. More extensive resection of the spermatic cord is advocated. The Chevrassu-Hilman operation yields poor results in malignancy of the testis, which condition should be treated by orchectomy and irradiation.

MISCELLANEOUS

Kashin, J. G. and Pinck, B. D.: Factors in Male Sterility. A Critical Review of 135 Cases. *Am. J. Surg.* 1944, 66: 346.

The present study was directed primarily to cases of male infertility not associated with obvious abnormalities such as hypospadias, cryptorchidism, and abnormal attachment of the epididymis to the testis. This study included a careful medical history with emphasis upon endocrinological and sexual factors, physical examination, and, when necessary, cystoscopy and catheterization of the ejaculatory ducts. Laboratory and x-ray examinations were made as indicated. At least two semen specimens were obtained by withdrawal and ejaculation into a glass container after five days abstinence, and examined within an hour or two for motility, volume, count, mucolysis, and differential morphology. The criteria of morphology were those of Pollak and Joel,

and the motility was expressed in per cent as the ratio to nonmotile forms which lie in one-quarter of the microscopic field through an Ehrlich ocular screen. The total sperm count was determined in the counting chamber with 4 per cent boric acid, and 1 per cent phenol as a diluent. A histological study of a seminal smear stained with Macheal tetrachrome stain was made. The normal values were motility 80 per cent after two hours, sperm count, from 60 to 150 million per cubic centimeter, and morphology less than 30 per cent of abnormal forms.

A detailed analysis of 135 consecutive cases of sterile marriages indicated that the greatest correlation existed between a decreased sperm count and an increased per cent of abnormal forms and infertility. Motility and viability did not appear important. In only 31 per cent of the 135 sterile marriages were the semen analyses normal. In 25 per cent of the cases there was a decreased sperm count, an increased number of abnormal spermatozoa, and usually a decreased motility. The authors believe it is in this group of cases that endocrinological factors are responsible for sterility and that testicular biopsy should be performed. In 25 per cent of the cases a normal sperm count was associated with a high percentage of abnormal forms, and it is in this group that the casual observer may pronounce a semen specimen normal unless special morphological studies are performed routinely. The etiology in this group is often obscure, but endocrine deficiency foci in infection, exposure to x rays, or dietary deficiency must be considered. Semen analyses by 2 recent gonologists showed normal counts and motility but there was a shift to the immature types of spermatozoa among the abnormal forms present—probably the result of stimulation of spermatogenesis. Aspermia was present in 24 (18 per cent) of the 135 cases. Among these 24, 10 patients had obstruction of the genital pathways due to past epididymitis, and 14 had defective spermatogenesis. Of those with defective spermatogenesis 3 had had mumps orchitis, 1 had a history of seminoma with x ray therapy and 3 were found to have endocrine dysfunction. In only 1 case was improvement noted upon treatment with thyroid, corticosterone and gonadotropins after two years of therapy. Impregnation was successful.

Treatment in cases of definite endocrine deficiency often was attended by dramatic results. However these cases were few. When hypothyroidism was present, thyroid medication gave good results. Gonadotropins were ineffective. Vitamin B₁, B complex, and vitamin E were given in large doses, alone and with gonadotropins but with no effect. Treatment of foci of infection was followed in some cases by improvement in the semen. In cases with excessive numbers of spermatozoa and an inordinate number of abnormal forms of the immature type, testosterone propionate (10 mgm. twice a week) caused a decrease in the total number and percentage of abnormal spermatozoa. Epididymovasectomy in cases of obstructive aspermia was unsuccessful. The

authors comment that their results in five years in 135 cases are discouraging as pregnancy resulted in only 11 per cent of the entire series.

The authors conclude that endocrine therapy plays a limited role in most cases of male sterility.

DONALD F. McDONALD, M.D.

Usher G. S., and Cowan H.: Venereal Diseases Among the Migrant Farm Laborers of New Jersey. *J. M. Soc. N. Jersey* 1945 42 11

1 Of about 2,800 migrant farm workers in the potato-growing section of New Jersey 756 were examined for venereal diseases. The examinations included blood tests and inspection for lesions and for gonorrhea. The women received routine gonococcus cultures.

2 The venereal disease rate was found to be very high especially in women from fifteen to twenty four years of age. In the latter group 63 per cent of those examined were found to have darkfield positive lesions of early syphilis and 30.6 per cent were found to have gonorrhea.

3 Most of these infections were "imported to New Jersey. The hazard to the areas through which these people travel and to the people of New Jersey is pointed out.

4. The living conditions of these workers are favorable to the spread of the diseases. These conditions urgently need correction.

5 Routine medical examination of all migrant workers and prompt application of rapid treatment methods are needed. Legislation to require such examinations and perhaps enforcement of the Interstate Quarantine Law would be helpful.

JOHN A. LOFF, M.D.

Exley M.: Penicillin Treatment of Sulfonamide-Resistant Gonorrhea with Results of Multiple and Single Injection Methods. *J. Urol., Balt.*, 1944, 52 626

Two hundred and fifty-one cases of sulfonamide-resistant gonorrhea were treated with varying amounts of penicillin.

The dosage varying from 41,300 to 125,000 Oxford units was administered by intramuscular injections.

The result of the asymptomatic cure by means of the single injection treatment is dramatic. The amount of penicillin used should be at least 80,000 Oxford units. The absorption-elimination time is short, and this method may later be found to be more efficacious in previously untreated gonorrheal urethritis.

Excess dilution is frowned upon for the intramuscular treatment. This not only causes needless pain at the site of the injection but also a more rapid rate of absorption. In another series being treated at present and to be published later this has been found to be true.

There were only 3 cases with toxic manifestations in this series all were transient and minimal in nature.

The follow up examinations on the armed-service cases comprising 77 per cent of this series, have all been negative by culture and smear. The follow-up of the merchant service has not been as satisfactory, but the total average time of examination in both groups was thirty-one and two-tenth days. An average of 2.8 examinations have been made after the discharge of the patient from the hospital.

The average time for the cultures to become negative in all groups was twenty-one and one-tenth hours. The change may have occurred earlier but it was inexpedient to make tests at more frequent intervals.

Although the number of cases in this series is small the use of penicillin is a gratifying addition to the curative armamentarium in the treatment of epididymitis associated with gonorrheal urethritis.

The combined use of hyperpyrexia and chemotherapy has yielded satisfactory results. There are still cases of failure in which this type of treatment will have to be utilized. The hospitalization time has been drastically reduced by the advent and substitution of penicillin.

An evaluation of the treatment from the results obtained leads the authors to believe that certain methods used in this series are the most satisfactory. They are inclined toward the multiple-injection treatment, their preference being either 2 injections of 50,000 Oxford units for a total of 100,000 Oxford units, or 5 injections for a total of 80,000 Oxford units. At the present time they are running a larger series of the latter group.

The total treatment period has been reduced to below nine hours by means of the multiple injection method.

The total dosage of penicillin has been reduced

From the observations made it does not seem desirable nor expedient, at this time to recommend

the one-day ambulatory treatment until further clinical studies have been made.

JOHN A. LOAR M.D.

Bowworth, N. L., Riba, L. W., and Schmicklapp, C. J.: Two Hundred and Thirty Three Cases of Sulfis Resistant Gonorrhea Treated with 50,000 Units of Penicillin. *J. U. & Balt.* 1944, 51: 631.

Fifty thousand units of penicillin is an insufficient dosage to clear the average male gonorrheal infection—the results are failures in 23 per cent of the cases treated by this dosage.

A high incidence of positive and doubtful smears occurs during the first fourteen post treatment days, but this indicates neither penicillin success nor failure. Positive smears and cultures usually indicate failure of cure.

Treatment with 100,000 units will clear the majority (85 per cent) of the 50,000-unit failures.

Hyperpyrexia and 100,000 intravenous units of penicillin will clear 30 per cent of the apparent penicillin-resistant gonorrheal infections. With an increase of penicillin supply larger doses may be indicated during fever treatment.

Gonococcus carriers may also be produced with penicillin therapy particularly when insufficient dosages are given.

One hundred and sixty thousand units of penicillin administered intramuscularly will result in the highest percentage (93 per cent) of clinical cures in the present-day treatment of sulfonamide-resistant gonorrheal infections.

Patients with complications should have correspondingly larger doses.

Penicillin is an excellent gonococcal bacteriostatic. The clinical cure occurs as a result of the host's defense mechanism provided it is not disturbed by too much interference. JOHN A. LOAR M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Boger W P: Pneumococcic Arthritis. Report of a Case of So-Called Primary Pneumococcic Arthritis. *J Am. M. Ass.* 1944; 126 1063

Pneumococcic arthritis should be regarded as the result of a septicemia.

A case of pneumococcic arthritis is presented in which no infection other than that in the knee could be demonstrated. A negro woman aged fifty was seized with sudden acute pain in the left knee. The next day the knee was swollen and painful on motion. During the following days the knee became more swollen and painful and the patient had a fever.

The patient was admitted to the hospital on the tenth day. The history showed no evidence of any previous infection. The temperature was 103 F the pulse rate 100, and respiration 25. The blood pressure was 125/85. The left leg was swollen from the hip to the ankle and was easily twice the size of the right leg. This increase in size of the leg was due primarily to a pitting edema limited to the dependent aspect of the leg from the left hip to the ankle. Large engorged veins were present over the patellar and lateral aspects of the knee and other signs of inflammation were present. There was effusion of the knee joint, the patella was ballotable, and the knee joint was very tender and hot to touch. Movement of the joint was painful and limited. Fluctuation was present. No lymphadenopathy was present in the left groin.

A diagnosis of acute septic arthritis was made. The first aspiration produced 310 cc. of thick yellowish-green pus from the knee joint, and examination revealed type XII pneumococcus in pure culture.

Sulfadiazine was given in full dosage. The patient's temperature subsided on the fifth day and was only slightly elevated after that. A second aspiration produced 340 cc. of pus. Five grams of sodium sulfadiazine dissolved in 100 cc. of distilled water was then injected into the joint. Aspiration was repeated on the sixteenth, nineteenth, and twentieth days but no organisms were found in the pus.

X-ray films did not reveal any bone destruction in the knee joint. The hemoglobin averaged 58 per cent and the red count averaged 3,410,000. One transfusion was given. The high white-cell count was 12,300 and all other counts averaged 7,460. The differential counts did not show more than 76 per cent polymorphonuclear leucocytes. Six blood cultures failed to yield a growth.

The patient was discharged on the thirty-second day with a painless knee joint and was able to walk without discomfort. The range of motion was 90 degrees.

The listed cases of pneumococcic arthritis are given. The classification of the symptoms, clinical

features, bacteriology, pathology treatment, and prognosis are discussed in detail.

RICHARD J BENNETT JR., M.D.

Boger W P: Purulent Meningococcal Arthritis. *Am. J. M. Sc.* 1944 308 708

Two proved cases of purulent meningococcal arthritis are presented and it is suggested that the prognosis in joint manifestations of meningococcal infections is not so uniformly favorable as is usually stated in the literature.

CASE 1: A fifty-two-year-old white widow entered the hospital with a temperature of 103 F. She complained of pain in every joint. Several weeks previous to entry the patient had been complaining of vague, coldlike symptoms with general muscular aching and nausea. Physical examination after hospital admittance disclosed a fine purpuric rash over the ankles and lower thirds of both legs, and in addition, several petechiae on the thighs and abdomen. Scattered over both hands, forearms, and feet were several larger purpuric spots which measured from 3 to 10 mm. in diameter. Resemblance was noted to erythema nodosum and to Haverhill fever. The general picture exhibited redness and swelling of spots redness and exquisite tenderness over both elbow joints, both ankle and wrist joints, and swelling of the hands and feet. There was a splotch of purple discoloration over each of the metacarpophalangeal joints and the dull red of inflammation about both wrists.

Aspiration of the left knee was done and approximately 50 cc. of thick, yellow pus was obtained. On smear countless numbers of both intracellular and extracellular gram negative diplococci were found. Later both the blood culture and the culture made from the joint fluid were reported as showing growths of meningococci. The organism was typed as a type I meningococcus by the National Institute of Health.

After nineteen days of therapy with sulfadiazine the white count was 3,200 the patient was running a mild fever and most of the joints had become painless, but the left knee was still swollen, and the right hand was still definitely swollen. The knee could be flexed beyond 90 degrees but it felt stiff. Grasping with the right hand was poor and the wrist could not be dorsiflexed.

The follow up of this patient revealed that on the eighteenth day from the onset of her arthritis the left knee still ached, the left ankle swelled after walking, and the right hand remained swollen. A roentgenogram of the right wrist revealed destruction and narrowing of the joint space due to infectious arthritis.

CASE 2: A white, single woman twenty four years of age, had been employed in social work for several months and had been visiting in numerous homes.

She was taken with a cold, headache, muscle soreness, and a rash. Examination revealed a temperature of 102° F., slight soreness of the muscles generally, mild headache and some nausea. The neck was slightly painful on anterior flexion. The skin presented a hemorrhagic rash limited to the arms and legs, and both palms and soles presented spots ranging from 5 to 10 mm. in diameter. A lumbar puncture was done and slightly cloudy fluid was obtained. This revealed 500 cells per cubic millimeter. Organisms were not seen on smear but culture of the fluid was positive for meningococci. A blood culture taken at this time was noted to be positive for meningococci. The left knee was somewhat swollen but the patient herself had not been aware of this fact. There was no pain on manipulation of the joint, but flexion was a trifle limited by a feeling of "fullness." There was no redness or tenderness. Aspiration was done and a thick, yellowish fluid was obtained which, on smear, revealed gram-negative diplococci. Culture of this fluid was positive for meningococci. The patient recovered without later sequelae under treatment with sulfadiazine.

JOHN W. BARNES, M.D.

Shank, R. E., Glider, H., and Hoegland, C. L.: Studies on Diseases of Muscles; Progressive Muscular Dystrophy; A Clinical Review of 48 Cases. *Arch. Neur. Psychiat.*, Chic., 1944, 51: 431.

A clinical study of 40 patients with progressive muscular dystrophy gave evidence of the hereditary nature of the disease. Fourteen of the 40 patients were from families in which other cases of the disease had occurred. There were examples of dominant sex-linked and simple recessive types of inheritance. Both pseudohypertrophy and atrophy existed in the affected muscles, with pseudohypertrophy most frequent in the large bulky muscles of the younger patients.

The early onset of the disease was demonstrated, the first symptoms having been noted by 63 per cent of this series of patients before the age of ten years. When the onset was delayed until late childhood or early adult life, the first muscles involved were frequently those of the scapulohumeral group.

The course of progressive muscular dystrophy was most rapid in patients with onset of the disease before the fifth year of life.

There were characteristic changes in the roentgenograms of patients with progressive muscular dystrophy. These alterations include conspicuous streaking of the soft-tissue shadows of affected muscle, delayed appearance of centers of ossification in the bones of the hands and in the epiphyses of the long bones, and demineralization of other bony structures.

The rate of excretion of creatine was greater and the rate of excretion of creatinine was less in boys with muscular dystrophy than in normal boys of the same age group who were maintained on diets of identical composition. These differences were increased when the subjects were fasting.

The concentration of creatine in the plasma of dystrophic children was greater than the concentration in the plasma of normal subjects. Levels of creatinine in the plasma were unchanged.

The creatine tolerance of children with progressive muscular dystrophy was not significantly different from that of normal children of the same age group.

The basal metabolic rate was low in children with the disease. The median basal metabolic rate for a group of 14 patients was 14.5 per cent of the normal standards.

The fasting level of the blood sugar and the response to intravenous administration of dextrose were essentially the same in dystrophic patients as in normal subjects. One patient with muscular dystrophy gave evidence of an increased rate of utilization of dextrose injected intravenously.

Patients with progressive muscular dystrophy were in positive nitrogen and phosphorus balance.

Within recent years various types of therapy, including treatment with aminocaproic acid, vitamin E and pyridoxine, have been proposed for progressive muscular dystrophy. After thorough trial, each of these methods has proved to be singularly ineffective. Any rational approach to the successful treatment of the disease depends on more specific information concerning its nature and the metabolic changes affected by it.

Grieve, J.: Congenital Subluxation of the Acromioclavicular Joint. *Lancet*, Lond., 1944, 247: 817.

Six cases of congenital subluxation of the acromioclavicular joint are described also a seventh milder case with gross deformity of the right acromion. The exact nature of the condition is still obscure.

Even 1 cm. of displacement of the clavicle may produce no disability. The emotional effect may be important.

ROBERT P. MONTGOMERY, M.D.

Brieda, P. C.: Tuberculosis of the Greater Trochanter and Its Bursae. *Radiology*, 1945 44: 32.

The author gives a brief review of the literature which indicates that tuberculosis of the greater trochanter and its bursa is a rare condition usually occurring secondary to tuberculous osteomyelitis of the greater trochanter. All writers agree that complete extirpation of all infected tissue, with immobilization of the affected part, followed by body-building postoperative care, is the treatment of choice.

The condition may occur in either sex and at any age although it is unusual in children. The most common complaint is mild pain in the involved leg with intervals of quiescence. Often there is a draining sinus in the region of the trochanter.

Examination shows slight swelling with tenderness to pressure but no heat or redness. There is no limitation of motion in the hip joint. Tuberculosis elsewhere in the body is quite common.

The lesion has a strong tendency to recurrence and in the later stages it extends to the neck and head of

the femur and even to the joint itself. When only the bursa is involved the percentage of cures is believed to be somewhat higher.

The first roentgen sign is a small fleck of calcium in the bursa or a minimal area of destruction in the outermost part of the trochanter which often can be demonstrated only with soft tissue exposure. Later a larger area of destruction is noted in the trochanter with osteoporosis of the adjacent bone. Sometimes an involucrum is found in the soft tissues lateral to the trochanter secondary to infection or injury to the periosteum either following operation or in draining sinuses of long duration.

The differential diagnosis includes simple nonspecific bursitis or osteomyelitis and certain osteolytic neoplasms.

The author observed 4 cases which are briefly described and illustrated with the respective roentgenograms.

T. LUCUTIA, M.D.

Keen, P.: Pellegrini-Stieda Disease in the Bantu. *Clin. Proc. Capetown*, 1944, 3: 331.

The author describes 17 cases of Pellegrini-Stieda disease in the Bantu. A total of 20 cases were observed in eighteen months.

The anatomy of the medial collateral ligament in the Bantu has been described and differences have been noted. It appears that the medial collateral ligament in the Bantu is a larger structure, the insertion of which into the condyle of the femur is intimately associated with that of the tendon of the adductor magnus. Its insertion into the tibia is similar to that of the hamstring muscles.

In addition, it was noted that there were cellular spaces around the tendon of the adductor magnus, particularly between this tendon and the vastus medialis, where a branch of the genicular artery passes forward. This space communicates with the upper insertion of the medial collateral ligament and could harbor a hematoma which might undergo ossification if osteoblasts were released by the trauma. This might explain the tendency of the ossified masses to extend upward beyond the limits of the medial collateral ligament.

In 10 of the 17 cases in this series, as judged from the roentgenological appearances the ossification had extended beyond the limits of the ligament. In 4 other cases the ossification did not appear to be in the ligament at all, and in only 3 cases did it seem to be entirely confined to the ligament. For details on the etiology Kulowski's paper should be consulted.

In the present series of Bantu cases the intimate connection with the adductor magnus tendon might account for the upward spread beyond the limits of the medial collateral tendons. This fact might also account for the frequency of this condition in the Bantu. The extra strain on the upper part of the medial collateral ligament where practically all the ossification occurs might be caused by the action of the adductor magnus which apparently has a direct connection with the medial collateral ligament in the Bantu. It is possible that the differences in anatomy

Fig. 1 Left, An average diagram.

Fig. 2 An average specimen in the Bantu.

might also account for the conspicuous absence of lesions of the internal semilunar cartilage in the Bantu.

It has been suggested that in the Bantu periosteal avulsion near the upper insertion of the medial collateral ligament is the commonest cause of this form of para-articular ossification.

The principle that the condition is a true post-traumatic lesion must be accepted on the evidence available.

In 1 case the first roentgenograph showed no abnormality but the second one, taken twenty three days later showed definite signs of ossification. With a soft ray technique the ossification would probably have been visible within eighteen days. Two other cases with negative roentgenographs at the time of the accident showed advanced roentgenological signs after ten weeks.

With the more extensive lesions in the Bantu permanent disability up to 20 per cent in certain cases may be expected. It should however, be remembered that spontaneous resolution in mild cases may occur.

The temptation to dismiss a case of knee injury as trivial if no roentgenological signs are found must be avoided, particularly in view of the rarity of lesions of the semilunar cartilages in the Bantu.

The importance of this aspect of knee injuries can not be too strongly emphasized.

Simon, H. E. and Sacchet, H. A.: Muscle Hernias of the Leg. Review of the Literature and Report of 12 Cases. *Am. J. Surg.*, 1945 67: 87.

The observation in 12 cases of muscle hernias of the leg form the basis of this report. Twelve case reports are given with a discussion of the etiology, symptoms and findings, the diagnosis, the differential diagnosis, the treatment, and the prognosis.

Muscle hernias of the leg are not of infrequent occurrence particularly in active young males as represented by soldiers. Such hernias are characterized by a soft, semifluctuant swelling which increases in size when the limb is dependent or the muscle is relaxed, and decreases in size or disappears when the leg is passively elevated and usually when the muscle involved is contracted. It is reducible on pressure, when a distinct fascial defect can be palpated.

There are three types: those due presumably to congenital defects, those due to direct trauma or to indirect muscle violence (usually single, large, and producing symptoms for which surgery is indicated) and the idiopathic type which appears spontaneously particularly after muscular activity is increased. The last type is usually small, often multiple, presents less severe or no symptoms, and frequently requires no treatment.

Conditions to be differentiated from these muscle hernias are localized varicose veins, lipomas, angiomas, and other tumors. Surgical treatment consists of reduction of the herniated muscle and repair of the defect, usually by fascia transplant or suture.

EMIL C. ROBITZKE, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Mowlem, R.: Cancellous Chip Bone Grafts; Report on 75 Cases. *Lancet*, Lond., 1944, 247-745

Seventy-five cases of cancellous chip grafting for the restoration of contour and of continuity in fractures of the facial and cranial bones, the mandible, and the tibia are reported. The results in all were successful, in spite of potential infection in some of them.

In all cases the graft is derived from the ilium. This bone is chosen for its relatively high cellular content and for its porosity. The fragmentation is designed to increase the surface area of the transplant and thus to create optimal conditions for survival of the greatest number of bone cells. The advantage of increased simplicity of the operative technique, although important, is secondary.

The ilium is exposed by an incision about 3 inches long, and its crest and outer plate are freed from their muscular and aponeurotic attachments. Occasionally this process is continued on to the inner aspect. A block of bone of sufficient bulk is then removed with an osteotome, and its cortical covering is discarded. The remaining cancellous mass is divided into chips of various sizes, usually about 1 by 0.5 by 0.3 cm. Irregular shapes are often useful, but it is undesirable to make the chips too small because excessive condensation is likely to occur.

The application of this principle may necessitate alternative methods of bone immobilization, but it simplifies operation and ensures much more rapid regeneration than the accepted methods of bone grafting.

The immediate survival of a bone graft probably depends on the establishment of a blood supply to its

contained cells sufficiently early to ensure their continued activity.

For mechanical reasons, this is unlikely to occur in cortical bones but is much more likely to do so in cancellous bone.

Fragmentation of the cancellous bone renders a greater proportion of its cells accessible to the blood supply and expedites its survival.

A considerable experience in the use of massive cancellous grafts from the ilium pointed to the probability that this type of bone survives from the beginning. The two most important facts underlying this belief are (1) the rapidity with which structural adaptation occurs, so that a new cortex is well marked on roentgenographic investigation in from eight to twelve weeks, and (2) the very high tolerance to infection which these grafts possess as compared with that of the more usual compact graft from the tibia.

GRAFTS FOR THE RESTORATION OF CONTOUR

The basic technique is always much the same. The graft depends for its survival on the blood supply and not on contact with existing bone. The correct contour is obtained by simply building up chips to the requisite levels. Fixation with a pressure bandage for from four to six days completes the procedure.

In all these cases operative technique has been much simplified, in that wide exposures, bevelling of cranial margins, accurate templates, tedious shaping of one-piece grafts, and difficult fixations have been eliminated. In their place is a restricted wound of access, and contour is regained by merely adding or subtracting the requisite number of bone chips.

GRAFTS FOR THE RESTORATION OF CONTINUITY

Thirty-six mandibular defects have been treated in which the loss has varied from $\frac{3}{4}$ inch to half the jaw the average being 3 inches. The bone ends are immobilized by dental cap splints or external bone pins, or both. Eburnated bone and scarred soft tissue are widely removed. The first step in the insertion of the graft consists in placing a distance piece of cancellous bone, about $\frac{1}{4}$ inch thick and $\frac{1}{4}$ inch wide, into position on the deep aspect of the bone ends. This has a twofold function—it prevents soft tissues from bulging out through the mandibular defect, and it protects the chips from movement transmitted from the floor of the mouth. The chips are then laid into position overlying the distance piece and overlapping the mandibular ends, and are arranged to produce the necessary contour. No fixation other than suture of a layer of subcutaneous tissue is carried out, and it is sometimes desirable in the presence of free oozing to insert a drainage-tube for forty-eight hours. Three of these grafts were carried out in the presence of a known opening into the mouth, and many within a few days of the cessation of discharge. None were lost. The average time between operation and the removal of all splintage is 26.75 days, and it must be stressed that the chips

themselves confer no mutual stability whatever. X-ray control shows that fusion begins to be visible between the chips and with the mandibular ends in about fourteen days and continues until the bone is almost indistinguishable from the normal mandible. Clinical rigidity precedes complete roentgenographic fusion, so that careful examination and not x rays are used to determine the point at which fixation can be discarded.

Five cases of extensive losses in the long bones, each associated with an overlying skin defect, have been treated on the same lines. Replacement of the skin defect has usually been the first step although this may sometimes be combined with the bone-grafting operation. In the limbs treated to date, sufficient control of the bone ends was conferred by previously applied plaster casts, and a window was left, through which access was obtained and this was closed at the end of the operation by a further application of plaster. This may not always be sufficient and actual skeletal fixation will then be needed. If this is so either some form of skeletal splintage or a modified bony internal fixation may be used to confer stability. The chips can then be added to produce new bone.

It must be pointed out that the distance pieces are cancellous strips less than $\frac{1}{4}$ inch thick, and that they in no way correspond with the usual type of alar graft. They are simply forms between and around which the contour of the bone is built up with chips. They do not even fit snugly into their slots in the bone ends and they are neither wired nor tied in position. It will be seen that the bone ends themselves are not only cut back to eliminate burned tissue, but also bevelled to provide the maximal bleeding surface for adhesion to and vascularization of the grafts. It is unnecessary and undesirable to jeopardize the blood supply to the bone ends by stripping back of the periosteum through which nutrient vessels pass and it is not justifiable to use power-driven saws or burns because they may create sufficient heat to damage the vessels and the bone cells, on the immediate response of which the whole process depends.

In the tibial cases the initial plaster was removed at the end of five weeks and replaced by a below the-knee walking plaster. This is done in an endeavor to ensure an early return to vascular normality in the limb. The time of removal of all splintage seems to vary with the length of the defect with the degree of vascularity obtained in the bed and with the stresses to which the graft will finally be subjected. A tibia with a 1 inch defect became rigid in ten weeks, while 2 other tibias with defects of more than 4 inches in length are still slightly springy at twelve weeks. In a personal communication Plewes, who has applied this principle to a number of cases of nonunion of the tibia radius, and ulna, without gross loss of bone, reports that all splintage has been discarded in a little less than seven weeks.

X-ray control in the tibial series here reported shows that the chips fuse with equal rapidity at the

ends and in the middle of the defect, but that those chips lying immediately beneath the surface, where the blood supply is indifferent, do not fuse as fast as those in the depths of the wound which are in contact with vascular muscle bellies.

It will be appreciated, therefore that in using cancellous chips the accepted standards of bone grafting are reversed. Instead of splinting the defect with a dense almost noncellular transplant which may also act as a bridge for osteogenesis or as a poor source of new bone—and for neither of these purposes is it histologically suitable—other methods of fixation are used and the defect is filled with a cellular mass, the survival of which will produce the requisite amount of new bone within a matter of weeks. The cases here reported appear to show that such a change of outlook is rewarded by increased operative simplicity decreased postoperative recovery time, and added certainty of results.

ROBERT P. MONTGOMERY M D

King, D : Internal Fixation for Lumbosacral Fusion. *Am J Surg* 1944 66 357

Recently the number of patients operated upon for the removal of displaced intervertebral-disc substance has increased tremendously and it has become apparent that some of these patients should

Fig. A, Posterior view of lumbosacral joint showing screws through lateral articulations and tibial graft secured to spinous processes. Multiple chip grafts are not shown. B, Lateral view showing tibial graft.

Fig. 2. Sacrum and arch of fifth lumbar vertebra (from above) illustrating direction of sacra.

be subjected to spinal fusion at the same time. Unfortunately the prolonged bed rest in plaster has always been a serious objection to the operation and deterred many people from it. The purpose of this article is to describe an operative technique for fusing the lumbar and lumbosacral regions which furnishes immediate rigid internal fixation and thus eliminates the necessity for external fixation and prolonged bed rest.

The patient is placed prone on a hinged table and the lumbar lordosis is partly obliterated by lowering of both the head and foot ends of the table. The midline incision extends well down over the sacrum so that the muscles can be detached from the dorsal surface as far laterally as the posterior sacral foraminae. With a sharp elevator the muscles and ligaments are quickly and completely cleared from the fifth lumbar spinous process and laminae, and partially elevated from the fourth. The latter maneuver is necessary to get good exposure of the fifth process. Interspinal and supraspinal ligaments, and all other soft tissues are carefully removed from the area to be fused. The lateral articulations are exposed by dissecting and scraping away of their posterior capsular covers and slight opening of their joint spaces by strong traction with bone hooks under the laminae. As much as possible of the

Fig. 3. Case 1. Roentgenograms taken fourteen months after operation. Right, Shows excellent posterior bony bridge.

articular cartilages is removed and then a flat, thin, flexible cautery tip is inserted into the joint and the remaining cartilage cauterized. The fifth lumbar spinous process is removed and put aside for use as graft material at the close of the operation. The sharp edge of the small osteotome or a small gouge can be used to make a notch in the middle of the cortical surface of the inferior articular facet of the fifth lumbar vertebra for the reception of the tip of a No. 31 drill. This is necessary to prevent "wandering" of the drill point when it begins to rotate. If the drill is directed downward and outward parallel to the inferior edge of the fifth lamina (Fig. 1), the resulting tunnel will pass through the middle of the two facets that make up the joint and on into the lateral mass of the sacrum (Fig. 2). A "vitallium screw" is placed in the tunnel and tightened, and the same procedure is carried out on the other side. Rigid lumbosacral fixation can be demonstrated by seizing the stump of the fifth lumbar spinous process with a heavy Kocher hemostat and lifting up and

The remainder of the operation consists in elevating multiple small bone chips from the fifth laminae

*For women and small men X (back long); for large men — back long

views (60 degrees) to show the lateral articulations. Note complete disappearance of joint spaces. (Courtesy of American Journal of Surgery.)

and the dorsal surface of the sacrum. Supplemental bone grafts from the ilium or tibia are always used by the author ilial bone being preferred. In an occasional case in which the spinous processes are well developed, a tibial graft has been fastened directly on top of the stumps (Fig. 1) with short vitallium screws. After closure several drain pads are snugly strapped over the wound with adhesive, but no brace or cast is used.

The patients are allowed to move about at will. Since internal fixation is rigid the amount of pain is minimal. Many of the patients are up and about in ten days, but the average is about three weeks.

In 1 patient there was persistent burning pain in the distribution of the fifth lumbar nerve root on one side which necessitated the removal of the screw. In a series of 30 fusions the authors have had one postoperative infection. The screws and grafts were removed during the second postoperative week. Three case reports are presented.

ROBERT P. MONTGOMERY M.D.

White, J. W., and Strubbs, S. G. Jr.: Growth Arrest for Equalizing Leg Lengths. *J. Am. M. Ass.*, 1944, 126: 1146.

The procedure presented in this report has been in use for ten years by the authors and has been found to be a simple and effective means of arresting the longitudinal growth of bones. In a series of 140 cases arrested before 1943 there were 302 separate growth arrests, the arresting of both bones below the knee being called one arrest procedure. Since that time more double arrests have been done, almost half the cases having had growth arrests both above and below the knee.

The operation employed in this series consists of the removal of a square core of bone and epiphyseal cartilage from the lateral and medial aspects of the distal or proximal end of the bone attacked with a slightly modified one half inch-square mortising chisel. The chisel is driven into the cancellous bone diagonally over the epiphyseal plate, a skin needle being used as a direction finder. The epiphyseal plate, if the operation is done correctly should divide the excised square plug of bone diagonally in halves. After being driven sufficiently deep the instrument is manipulated so that the square plug of bone breaks off in the depth of the hole, and the chisel containing the plug is extracted. The parts of the plate adjacent to the hole are thoroughly curetted, and the chisel still containing the plug is rotated 90 degrees from its original position and inserted into the hole. With an obturator the plug of bone is driven out of the chisel into the hole. Thus the fragment of the epiphyseal plate in the plug of bone is rotated 90 degrees from its original position which produces a deep bone graft bridging the cartilaginous gap. This procedure is carried out on either side of the femur or tibia but the fibula needs to be attacked only from its lateral aspect. The joint is immobilized in plaster for a period of three weeks.

In order to record discrepancies in leg length more accurately than can be done with a tape measure, x ray films of the patient's pelvis are made with his feet forced firmly down against the foot board at the end of the Bucky table and a standard tube distance. The difference in height of the femoral heads from the transverse foot board is recorded as the difference in length of the legs. The same error is present in all the films and as all calculations are based on these films the error cancels itself. These films have proved to be valuable and accurate records.

A simple method of calculation sufficiently accurate, in the face of so many variable factors associated with bone growth is presented. Regardless of the age and sex of the child the authors calculate that a growth arrest procedure at the distal femoral epiphysis will retard growth at the rate of $\frac{3}{8}$ inch a year while at the proximal end of the tibia and fibula it will retard growth $\frac{1}{4}$ inch. They figure that growth ceases in boys at seventeen and in girls one year earlier. These figures have proved sufficiently accurate in a large number of cases. These methods of calculation and of keeping records, as well as the operative procedure are recommended because of their effectiveness and simplicity.

JOHN L. LUNDQUIST M.D.

FRACTURES AND DISLOCATIONS

Sirls, I. E.: External Pin Transfixion of Fractures; An Analysis of 59 Cases. *Ann. Surg.*, 1944, 120: 911.

The author reports the results of his experiences with the use of external pin fixation in the treatment of 80 cases of fractures during the past three and one half years at the Bellevue Hospital in New York. He believes that the high incidence of discharge around the pin sites alone is sufficient reason to preclude the use of the method as a routine procedure. Many of the infections around the pin sites might have been averted by laying less stress on ambulation and mobilization of the joints, by immediate immobilization of the extremity and pins in plaster and by the application of a new encasement when the swelling had subsided. The high mortality in hip fractures might have been prevented by the use of internal instead of external pin fixation. In the author's opinion external pin fixation should not be used in the treatment of fractures of the hip. External mechanical fixation with plaster is useful if it is restricted to certain problem fractures in which conservative treatment will not give a satisfactory clinical result.

The author calls attention to the fundamental principles in the application of external pin fixation which have evolved as a result of the use of this method by proponents, and as a result of his own experience. He describes the procedure of reduction for simple and compound fractures, the complications, the incidence of infection at pin sites and the time required for these sites to heal the relation

of the healing time of the fracture to the time required for the pin sites to heal, the time required for the healing of fractures treated by external pin fixation, and the indications for the use of external pin fixation.

A number of illustrations and several tables accompany the article.

As a result of his experience with these 80 cases the author believes that the high incidence of discharge from the pin sites (46 per cent) of osteomyelitis of the pin sites with persistence of discharge long after the fracture had united (22.5 per cent) and of death (10 per cent) should preclude the further use of the method as a routine procedure for fractures of the long bones and of the neck of the femur. The procedure should be used only in selected cases, and by those who have been especially trained in the technique. The potential danger of infection at the sites of the pin insertions transcends the dangers of distraction, delayed union, and nonunion. The method should be restricted to certain problem fractures and to persistently displaced compound fractures in which, by visual manipulation, the reduction can be facilitated and maintained until a properly fitting encasement can be expected to maintain the realignment of the fragments. Ambulation and early mobilization of the joints should not be the motivating factors for the use of external mechanical pin fixation.

Infection of the pin sites with distraction and delayed union are attributed to (1) ambulation and motion of the joints without plaster (2) function of the soft tissues against a pin which causes the infection and osteomyelitis (3) pressure necrosis of the bone caused by a pin which impairs the stability of the fixation this permits a continuous hyperemia of the fracture site with absorption of the ends of the bone, and results in distraction of the fragments (4) the prolonged use of the pins (5) failure to immobilize adequately the extremity and pins in plaster and (6) failure to reapply a more snugly fitting encasement when the swelling subsides.

ERIC C. ROSSITER, M.D.

ORTHOPEDICS IN GENERAL

Parkins, J. E.: The Epidemiology of Poliomyelitis. *N. York State J. M.* 945 45 159.

The present knowledge of the spread of poliomyelitis is similar to what we knew about eighty years ago with regard to cholera and typhoid fever. At that time physicians concluded that cholera and typhoid fever were caused by drinking water polluted by the excreta of infected individuals. This theory proved to be a fact years later when the cholera and typhoid-fever organisms were discovered.

Poliomyelitis is caused by a filtrable virus. In the absence of a suitable laboratory animal considerable difficulties have been encountered in direct laboratory experimentation. Most of our knowledge of the spread of poliomyelitis depends entirely upon epi-

demologic evidence. There are apparently several ways of spreading poliomyelitis. The usual manner of spreading poliomyelitis is discussed in this article. In order to understand the epidemiology of poliomyelitis it has to be borne in mind that only a small number of cases affected by poliomyelitis develop paralysis. In areas where poliomyelitis appeared in epidemic form the virus was found in the stools of many persons who had never shown any symptoms of paralysis. Another interesting observation in connection with susceptibility to poliomyelitis is the observation that in a community that had once been affected by this disease new cases of poliomyelitis are very rare. The same condition could be observed in the case of measles and other diseases with a high rate of infection and with a high degree of immunity resulting from the infection.

It has been accepted that the disease is spread by man himself. It is conceivable that the virus might be harbored by animals and insects under certain unusual circumstances. The actual portal of entry in poliomyelitis is the pharyngeal mucosa, and at times the lower intestinal tract. Faber, Silverberg, and Dong reported that in their experiments with cynomolgus monkeys, invasion of the central nervous system had been via the trigeminal nerves and via the sympathetic fibers of the nasopharynx. The peak of poliomyelitis usually occurs in the summer when also certain insects are prevalent. It must be stressed, however, that the prevalence of the infection in summer time does not exclude person-to-person spread of the disease. Although poliomyelitis is rarely seen in the cold season, the statement that poliomyelitis disappears as soon as there is a frost is not correct. Another factor in doubting that poliomyelitis is usually spread by insects is the fact that malaria, a disease known to be spread by insects, does not follow the clinical, laboratory, and epidemiological pattern of poliomyelitis. The poliomyelitis virus has been demonstrated on flies. These flies apparently come in contact with human excreta. The fact that the elimination of horse stables and privies in larger cities did not eliminate the disease indicates that flies have very little bearing on the spread of the disease. It has been clearly shown that water has no influence in the outbreaks of poliomyelitis in certain regions. In the years 1916 and 1915 it was found that raw milk was the means of transmission of poliomyelitis in only 7 or 8 cases. Since that time a considerable amount of evidence has been accumulated to show that milk is not usually involved in the transmission of poliomyelitis.

In considering the transmission of the disease through person-to-person contact, it was frequently possible to demonstrate the radial spread of poliomyelitis. This has been observed in many other respiratory-spread diseases, for example, measles. The fact that poliomyelitis is more frequently seen in rural communities might be explained by the fact that in larger communities the encounter with a poliomyelitis virus takes place at an early age. It is likely that for this reason there is a certain amount

immunity against the disease. In smaller communities there is less contact between individuals, and the first encounter with this disease usually occurs at an older age.

In considering effective control measures, based upon the theory of person-to-person spread, rigid isolation of the affected individuals would be indicated. The effectiveness of this program is limited when one considers that ordinarily only analytic cases are reported to the Health Department. These cases, however, account for only a small portion of affected persons, and by the time because is reported the patient usually has had ample opportunity to spread the disease. Parents living in the affected areas are advised to keep their children from gatherings and to avoid contact with children that show any signs of illness. Overfatigue, chilling, and tonsillectomy should be avoided in an area in which poliomyelitis is occurring. From a scientific point of view there might be some doubt as to the wisdom of postponing the first encounter with the virus for adulthood. Effective control of poliomyelitis would be accomplished through a safe vaccine. Unfortunately the methods employed to kill the virus in the vaccine also destroy its anti-toxicity.

Investigators in Chicago have developed an effective vaccine against the homologous mouse adapted Lansing strain. This vaccine was produced by a newly developed method of ultraviolet light irradiation. Before accepting this vaccine over enthusiastically for human beings it must be tried on many more mice and many more monkeys and on many more strains of poliomyelitis. It is possible that in a few more years the problem of poliomyelitis may be solved by active immunization.

GEORGE L. REESE, M.D.

Logan, L. S.: Practical Points in Plaster Techniques; Two Years of Experience in Forward Surgery with a Royal Army Medical Corps (Mobile) Casualty-Clearing Station 1941-1943. *Surgical New Zealand J Surg.*, 1944, 14, 75.

The surgeon in forward areas fulfils two main functions: (a) the saving of life from immediate and grave battle injuries, and (b) the treatment of many other wounds, chiefly injuries to muscles and compound fractures. The first function will occupy some 75 per cent of his time. The permanent relief of pain and the minimization of sepsis in an already infected wound stand out prominently among the objectives of surgery as practiced in a casualty-clearing station. The surgeon there needs few instruments and little academic knowledge, but above all he requires experience. With experience come many tricks of the trade which make his work easier and more effective. Complete immobilization may be regarded as the keynote of all. It banishes pain, overcomes shock, lessens sepsis, and allows healing to begin while the patient is still far from a base hospital where more effective measures are possible. Complete immobilization is just as necessary for

fractures or injuries of the muscles and skin as it is for those of bone.

Loose army plaster of Paris This is the most useful of all. It is easy to carry in bulk, is of good quality and is easy to make up into bandages of any width. It is slightly slower in setting than Cellon, and is cheaper. Indeed the best plasters were made from alternate bandages made with loose plaster of Paris and Cellon.

A plaster must be strong to serve its purpose. Often on the arrival of a convoy broken and, therefore pain producing plasters were observed. Lower limb plaster cases usually break just about the ankle or just below the knee and they should therefore, be made stronger in these locations. Greater strength in these locations is required in a plaster used for travelling than in one put on at a base hospital.

Slabs are always broken and are therefore mentioned only to be dismissed.

Adequate length is another important feature. Many plasters are too short, and as a result do not fulfil their function. Many patients come with the toes unsupported and therefore are subject to pressure from the blankets. Plasters for the lower leg arrive with the plaster prolonged about 4 inches above the knee. This part usually softens and, the limb having shrunk a little, movement at the knee readily takes place. It is better therefore to carry these plasters higher—indeed as a routine up to the groin—in order to avoid a painful limb. Application from the groin to beyond the toes is advised.

Adequate padding is also important. Opinions on this subject differ markedly and the author's casualty-clearing station has undergone a reversal in technique from the completely skin-tight closed plaster to a split, lightly padded cast. The artistry of the nonpadded cast has given way to the safety of the padded cast. They have however always used felt over the heel and the malleolus; particularly the heel, for it is of little avail to have the tibia and fibula united at the end of ten weeks if the slough over the heel has not yet separated. It is thought better thus to play for safety for once the patient leaves the casualty-clearing station the delays may be of almost any length until the next hospital or medical area is reached. When wool is not available, split Gamgee has been used. It is not so good but can be made to answer the purpose.

Finally a plaster must be easily and painlessly removable. Such incidents as the swelling of a limb at a bony point becoming painful or some similar misfortune may arise at any time and call for immediate removal of the plaster cast. Padding prevents unshaven hairs from sticking to the plaster and the use of the greased pig makes splitting and therefore removal easy. The greased pig is a thick round rubber tourniquet liberally smeared with vaseline which is laid on the limb after the limb has been covered with wool. The plaster is now applied in the usual way over the tube and when it has just set the tube is pulled out, an elevated tunnel thus being left down the whole length of the cast. This is cut open

at once, 2 inches being left intact at each end for the purpose of holding the ends of the plaster together. Should now an urgent removal of the plaster become necessary it is a simple matter to cut the two ends. The splitting of the plaster allows of expansion of the limb to minor degrees, and thus makes the cast safer without the loss of any of its powers of immobilization.

Each patient in plaster should be kept at the station for two days if possible. The first day is for thorough drying and setting, and the second to make sure that the plaster is comfortable. Every complaint about pain in a limb in plaster should be listened to. Pain means that something is wrong, and when pain is present plasters should be reapplied until they are comfortable.

The chief causes of trouble in plasters for wounds of the hand and wrist are the slabs are too thin and break at the wrist they are not molded around the arm to grip it they do not in certain cases extend beyond the finger tips to protect them against jarring, and circular plasters cause stiff fingers and often swelling beyond. To avoid these troubles, the wound is attended to in the usual manner and a wet, shrunk bandage is applied around the arm down to the hand. A thick, long, wide slab is made and applied over the volar surface of the arm from just distal to the elbow joint to well beyond the finger tips. It is molded around the arm and into the palm, with the hand slightly dorsiflexed. The piece projecting beyond the finger tips is then bent back dorsally and heaped up to form a small bar just distal to the finger tips. The rest is molded back to strengthen the wrist part. The rim thus formed distal to the finger tips prevents movement, and injury and makes a comfortable support in which the fingers can move if this is desired. A cast of this type is extremely useful in all inflammatory infections of the hand, and is recommended for these it can be modified to suit conditions. However in the main it stops pain, limits infection, and allows early resolution.

PLASTERS FOR FRACTURES IN THE LOWER LIMB

To avoid the usual troubles a plaster cast is applied in the following manner:

The limb is held in abduction, extension, and slight flexion at the knee, with the foot in planter flexion. Cotton wool in rolls is applied from the groin to the toes. Three pieces of felt are held ready one for the heel and one for each malleolus. The greased tourniquet is laid lengthwise down the limb over the wool, the metal end being caught between the first two toes and the other end being left at the groin. The plaster is applied first at the thigh and a strong and adequate case is made. A pause is made after the knee is covered so that the plaster may set with the knee in slight flexion. The rest of the plaster is then applied to the toes, the heel traction being kept up and care being taken that the foot is in the neutral position. A slab is now made about 20 inches long, out of two 6-inch bandages. It is applied to the back

of the calf and up to the toes, so that 6 inches overlap the toes on the dorsal aspect. The slab is bound to the cast up to the toe level, after which the 6-inch overlap is turned back to the planter surface, the slab thus being doubled and a shelf being left projecting 1 inch beyond the toes. A small slab of "Cellon" about 10 inches long, made from 4-inch bandage, is laid across the end of the major slab. The ends of it are then brought down on each side of the foot. The plaster is finished with one 4-inch bandage. This plaster is an adequate one, the toe cap never breaking. The toes should be seen to be capable of full movement.

PLASTERS FOR LARGE WOUNDS OF THE THIGH AND FRACTURED FEMUR

From a casualty-clearing-station standpoint, the only type of immobilization which has stood the test of desert travel is the "Tobruk plaster." Immobilization is the only principle of importance as far as the casualty-clearing-station treatment of fractured femur is concerned. The Tobruk cast produces the best immobilization possible, and therefore extension is unnecessary in the author's opinion. Some still desire it and therefore it has been included in the technique.

The wound is attended to and dressed. A suitable Thomas splint is chosen and bent at the knee, and slings are made. For those who desire extension, the leg is shaved and strapping is applied from the mid-thigh to beyond the toes, padding being put between the strapping and the malleoli. The whole limb is padded with wool and a complete plaster is applied from just distal to the groin to the toes, the knee being included in a slightly flexed position, the toes with a good stout toe support, and the foot in a neutral position. A "greased pig" is used to allow of splitting. A felt pad is placed under the heel. The encased limb is now put into the Thomas splint. The ring is pushed well against the ischium and well into the adductor region. Care is taken that the bend in the Thomas splint corresponds to the flexion of the knee. Three shell dressings are now used. One is pushed between Scarpa's triangle and the ring, and the other two are placed between the outer aspect of the thigh and the ring. The ends of the extension strapping are now tied and fixed to the end of the Thomas splint by a cord. A Spanish windlass is inserted and twisted tight. The leg encased in a complete cast is now fixed immutably to the Thomas splint by three 4 inch "Cellon" bandages. One is placed at the ankle, one at the knee, and one at the ring, the shell dressings being first taken in so as to fix them. The "greased pig" is withdrawn and the cast is cut, the customary 5 inches being left at each end. A Sinclair's footpiece (the iron hoop) is now firmly fixed to the end of the Thomas splint by a plaster bandage. This does away with the stretcher bar and allows the patient to be nursed in bed and handled easily in air transport. It supports the splint and the limb perfectly when its foot is put between two folded blankets.

In the case of fractures of the femur, high in the shaft or at the neck, the author has used a technique similar to that described, but has prolonged the cast proximally so that it follows the line of the groin to the iliac crest, thus grasping the trochanter. The ring of the Thomas splint in this case will not slip over the proximal end of the plaster but rests on it. Any attempt, therefore, at extension is impossible. This method combined with the use of a stretcher bar, to anchor the distal end of the limb firmly allows the patient to travel comfortably.

The points in favor of this method are

1. There is no rotation of the limb inside the plaster for the limb and foot are encased
2. The foot cannot drop or twist and the toes cannot become painful because all are supported at the same time free toe movement is allowed
3. The raw surfaces of the wound itself are given immediate support.
4. Practically no hip-joint movement can take place if the end of the spint is fixed.
5. The method is simple, quick, and always has been efficient in the author's experience.

PLASTER FOR WOUNDS OF SHOULDER GIRDLE AND HUMERUS THE THORACOBRACHIAL CAST

On the patient's arrival, an anesthetic is given the wound is treated and dressed and the limb is bandaged to the side of the chest wall with a strong band bandage, the arm being kept in flexion. Next morning the following preparations are made.

One hour before the patient is brought to the theater morphine ($\frac{1}{4}$ gr) and scopolamine are given. A further dose of morphine is given intravenously. The patient's co-operation is sought by explanation as to the procedure. He is made to sit up in the stretcher and the bandage over the forearm put on the night before is cut off. The forearm is now bandaged with the wet bandage and a good volar slab is applied to the heads of the metacarpal bones. This is allowed to set hard being the permanent hand support. The patient is now made to sit on a stool. His feet are widely spaced to get a good base, with someone holding his hand firmly. The rest of the previous night's bandage is removed quickly the whole arm being freed and incidentally considerable pain is caused for the time being.

A large pad of felt is applied over the injured shoulder girdle, care being taken that it covers the

spine of the scapula, the lateral aspect of the humerus, and the clavicle. Three shell dressings do equally well for this purpose. Over the olecranon a thick felt pad is applied and everything is bound on, two rolls of cotton wool being put in the gutter between the chest and the arm. The author uses two 6-inch bandages for this in a modified Velpeau technique. The arm is kept flexed with the elbow brought forward toward the midline. The forearm is kept free from the bandage and is kept held with a slight forward rotation to allow room to work between it and the chest wall.

The plaster is now applied a triangle being made with the base extending from the base of the neck to the olecranon on the injured side, and with its apex under the opposite axilla. Slabs are used to strengthen this. One extends from the base of the neck to the olecranon and embraces it. The other extends from the vertebral groove, passes around and forward to wrap around the lower and outer third of the humerus.

The whole humerus is now completely encased and all that remains is to fix the forearm by means of a plaster sling in a flexed position over the front of the chest. With a 6-inch bandage a start is made over the injured shoulder a sweep is made downward over the flexed forearm, underneath it, and then up under the opposite axilla, and so on to the original starting point. Three bandages suffice for this purpose.

At this stage the patient is no longer in pain. In contrast to his former condition one of considerable anxiety and pain he can now get up and walk away if too much morphine has not been given to allow it.

The fixation of the humerus. Additional points of importance in the fixation of the humerus are the following

The apex of the plaster under the opposite axilla should be made narrow and firm. The cast should be kept as high as possible, so that it does not chafe the abdominal wall when the patient is in the sitting position. There should be free movements of the fingers and support for the hands. The whole cast should fit snugly and allow little or no movement between the body and the cast.

The application of a thoracobrahial cast is the most dramatic procedure a casualty-clearing station ever does for a conscious patient.

ROBERT P. MONTGOMERY M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Fleming, B. J.: Mesenteric Vascular Occlusion. A Presentation of 15 Cases. *Am. J. Surg.* 1944, 66: 68.

Since 1895, when Eliot reported the first successful resection of the small intestine for mesenteric thrombosis, each year adds several reports of cases on this subject. This disease has a comparatively low incidence. A study of the literature on mesenteric occlusion reveals that the number of cases cannot be tabulated exactly.

To date it appears that about 554 cases of this disease have been reported in 32 of which resection was successful. At Kings County Hospital, Brooklyn the author encountered 5 cases during his surgical service. Further investigation revealed that 10 cases diagnosed at autopsy or at operation, had been recorded at Kings County Hospital from January 1935 to December 1943 which gave 15 new cases. Among these cases 3 operative survivals are recorded. This brings the total number of successful resections to 35.

As a general statement, it may be stated that the predominating cause of mesenteric occlusion in younger patients is found to be heart disease or infection. In older patients degenerative or premalignant conditions appear to be important etiological agents.

Attempts have been made to outline a clinical syndrome which might serve as a basis for the early diagnosis of mesenteric occlusion. Some believe that venous mesenteric occlusion can be segregated clinically from the arterial type. As it is very difficult to diagnose mesenteric vascular occlusion preoperatively or before death, it can be appreciated how much more difficult it is to differentiate the venous from the arterial type.

The belief that cardiac disease, especially auricular fibrillation, is a prerequisite for superior mesenteric arterial occlusion is not held by the author on the basis of his experience.

No pathognomonic findings are known. The onset of an acute surgical condition of the abdomen in an elderly patient may suggest this disease. Shock is more pronounced than in most other abdominal conditions with the exception of pancreatitis. Pain is out of proportion to the physical findings. Physical findings are usually variable degrees of tenderness, rigidity distention and absence of peristalsis. A previous fallacy was the fact that cardiac irregularities and bloody stools were considered necessary in the clinical picture of this entity.

In this series, occlusion occurred more frequently in the superior mesenteric vessels than in the inferior mesenteric vessels. Conservative therapy in cases of mesenteric occlusion is ineffectual treatment. Surgical intervention with radical resection of the involved

loops (beyond the areas of edema) is the only hope for cure.

The author's mortality rate was as high as that reported elsewhere. This mortality ranges from 60 to 90 per cent, and is due to shock and loss of blood. The author believes that the appalling mortality associated with this disease can be lowered only by improvement in diagnosis.

Treatment is of no avail in those cases in which occlusion of the superior mesenteric artery produces gangrene of the entire small intestine. Treatment is also ineffectual in cases in which the patient's general condition is so desperate (due to shock, heart disease, toxemia, or liver damage) that any operative procedure cannot be contemplated.

JOHN E. KIRKPATRICK, M.D.

Imler, A. E., Beaver M. G., and Sheehan, W. G.: The Value of Venography in Varicose Veins. *Am. J. Roentg.* 1944, 52: 5-4.

Venography is a valuable aid in the diagnosis and treatment of the following vascular diseases of the lower extremity: thrombophlebitis, pulmonary embolism, arteriovenous fistula, venospasm and varicosities.

The authors in this report are concerned with the efficacy of venography in selected cases of varicose veins. Ten per cent of healthy adults suffer from superficial varicosities. Before obliterating the superficial veins it is taken for granted that the deep veins are patent. The standard examinations (Perthes and bandage tests) for patency of the deep veins will prove adequate in the great majority of cases. However in order to prevent the recurrence of varices, a careful consideration must be given to the existing conditions. Recurrent varices may be due to technical errors or deep venous obstruction and stasis. Superficial varicosities associated with deep venous obstruction are compensatory and their obliteration will be promptly followed by a recurrence. In such instances the clinical patency tests may be normal and as a result may be misleading.

As contrast medium, a 35 per cent solution of diodrast is used. All patients are tested for diodrast sensitivity. Although the technique is not described in this article, it has been thoroughly described in a previous article (Papper, E. M., and Imler, A. E. *Surgery* 1944 15: 403). Three cases are reported in detail.

It is the opinion of the authors that positive evidence in venographic studies will defer surgical interference that might result in a permanent aggravation of symptoms and a recurrence of varicosities. Venograms are indicated in those patients suffering from varicose veins with a history of thrombosis or thrombophlebitis, pain and fatigue on walking or standing, edema or symptoms of orthostatic collapse, or major vascular anomalies.

MAURICE D. SACHS, M.D.

Shapiro, M. J. The Preoperative Diagnosis of Patent Ductus Arteriosus. *J Am M Ass* 1944, 126 934.

The author notes that since it is now possible to cure a patent ductus arteriosus by surgery it is of almost importance that the correct diagnosis be made, lest patients be subjected unnecessarily to a major surgical procedure or those with this lesion be denied the possibility of surgical cure. Two types of patency of the ductus may occur. The duct may remain open as part of a serious developmental defect and be the only means by which the circulation can be carried on in a heart seriously impaired by congenital defects. Such patients have evidence of congenital heart disease. In the type of case which is curable by surgery, the patent ductus is the only defect present, and the heart is otherwise normally developed. Strictly speaking, the uncomplicated isolated patency of the ductus is not a congenital lesion as it occurs after birth and has nothing to do with developmental defects of the heart. In the normal newborn infant, the ductus closes within a few minutes after the first breath is taken. Recent studies suggest that failure of closure in uncomplicated cases of patent ductus arteriosus may result from lack of oxygenation of the blood, possibly because of obstruction of the air passages in the newborn child.

The author discusses in detail the sex and age incidences, the clinical characteristics and the electrocardiographic and x ray findings in the 62 patients in whom a definite diagnosis of uncomplicated patent ductus arteriosus could be made. In 23 instances, there was an opportunity of checking the diagnosis. The diagnosis was correct in each instance.

The diagnostic criteria of patent ductus arteriosus may be summarized as follows: (1) machinery murmur (2) thrill in pulmonary area (3) enlarged pulmonary artery, (4) enlarged and pulsating pulmonary vessels (5) enlarged heart (6) increased pulse pressure (7) stunting of growth (8) absence of cyanosis and clubbing of fingers, (9) normal electrocardiogram and (10) history of heart disease from early childhood.

In the differential diagnosis, several cardiac conditions may be confused with patent ductus arteriosus. One of the most important, especially in infants and young children is the so-called venous hum in which there is also a continuous murmur heard over the base of the heart. It is usually not as loud as the characteristic machinery murmur. Occasionally, the diastolic murmur of aortic regurgitation will simulate the machinery murmur. In aortic regurgitation however there is invariably a pause between the systolic and diastolic murmurs. These murmurs are usually heard lower down along the left border of the sternum.

Patients with interauricular septal defects commonly exhibit x ray changes which simulate the findings in patent ductus arteriosus. On fluoroscopy the contour of the heart may suggest that found in patent ductus arteriosus however in most instances

the heart is considerably larger and more rounded in patients with interauricular septal defects.

In conclusion the author notes that the diagnosis of patent ductus arteriosus can be made without error. Patients should not be referred for surgical treatment unless they show the characteristic machinery murmur. The only exception to the rule is the occasional patient with a large patent ductus who may exhibit no murmur. Patients with cyanosis and clubbing of the fingers do not have uncomplicated patent ductus and they cannot be treated surgically. Pronounced electrocardiographic changes are not a part of the picture of simple patent ductus arteriosus.

HERBERT F THURSTON M.D

Bettman, R. B. and Tannenbaum W. Ligation of Patent Ductus Arteriosus in the Presence of an Apparent Bacterial Endocarditis; Report of a Case Apparently Cured. *Ann. Int. M.*, 1944, 21 1035

The authors report in detail a case in which ligation of a patent ductus arteriosus was done in the presence of an apparent bacterial endocarditis in a young woman eighteen years old. Two years after the operation the girl is well, healthy and to all appearances is living a normal life.

The feasibility of ligation of a patent ductus arteriosus was first demonstrated by Gross. The fact that such ligation in the presence of what appears to be a bacterial endocarditis may result in the cure of the disease was definitely established by Tourouff and confirmed in several other reports. Inasmuch as medicine operates very much as law on the basis of precedent, it will take an accumulation of statistics from many cases before the medical profession in general becomes cognizant of this new therapeutic procedure. Therefore the authors state their purpose of publishing the results of ligation of a patent ductus in the presence of bacterial endocarditis as they observe them.

HERBERT F THURSTON M.D

Nixon, J. W. Surgical Ligation of a Patent Ductus Arteriosus Associated with an Aneurysm of the Pulmonary Artery. *J Thorac Surg.*, 1944, 13 513.

The author failed to find in the literature a report of successful surgical treatment of a case of an aneurysm of the pulmonary artery associated with a patent ductus arteriosus. This fact led him to report the following case.

A nineteen year-old white female was admitted with the chief complaint of dyspnea on exertion and a diagnosis of a patent ductus arteriosus. The patient's past medical history was negative except for a humming and roaring in her chest which was present since early childhood and was more pronounced when she was lying down. She tired easily and when exerting would develop palpitation, dyspnea and precordial pain. Physical examination was negative except for a thrill over the pericardial region and a to-and-fro machinery murmur transmitted to the left axilla and back.

Fig. Left, Position of pericardium as it is normally reflected from the pulmonary artery. Right, Pericardium reflected from the aorta as found in this case.

Laboratory findings were essentially normal. The patient was operated on under intratracheal cyclopropane anesthesia through the usual anterior incision over the left second intercostal space. When the pleural cavity was opened an expansive pulsating mass was encountered within the pericardium extending upward in the region of the aorta. The pericardium, instead of being attached to the pulmonary artery as is usual was attached to the inferior surface of the aorta and thus overlay the ductus (Fig. 1). On incision of the pericardium the mass was shown to be an aneurysm of the pulmonary artery and only after the aneurysm was retracted downward could the ductus be exposed and dissected free. The ductus entered the aorta at a marked obtuse angle—a factor undoubtedly contributing to its patency. When the ductus was ligated with No. 8 braided silk, the thrill and murmur disappeared and the pulsation of the aneurysm markedly diminished which indicated that the blood flow through the ductus under aortic pressure exerted an increased strain on the aneurysm wall. No attempt was made to deal with the aneurysm. The pericardium was closed with cotton sutures and the ribs with wire sutures. The patient had an uneventful rapid recovery with discharge on the eighth postoperative day. There was some laryngeal nerve injury due to the extensive dissection required to locate and free the ductus. The hoarse voice had disappeared by five weeks and the patient was working as a clerk with marked improvement in the dyspnea.

Although patent ductus arteriosus is next to patent foramen ovale as the most common congenital cardiac defect, aneurysm of the pulmonary artery associated with it is rare. Only 11 cases of aneurysm of the pulmonary artery were reported in the literature from 1833 to 1930 and a patent ductus was present in 33 per cent of these cases. The pulmonary hypertension associated with patent ductus has been regarded as a cause of pulmonary aneurysm, but

since patency of this passage is common without aneurysm, it seems reasonable to assume that some additional lesion must contribute to its production. Syphilis has been considered also as an important causative agent.

Dilatation and thinning of the pulmonary artery may be present in cases of patent ductus arteriosus, but a true aneurysm is rare. This amount of thinning seems to depend on the diameter of the ductus and the completeness of its patency.

The failure of a ductus to close at birth is probably due to its position and direction. It usually enters the aorta at a right angle but as the acuteness of the angle decreases it becomes more exposed to intra-aortic pressure. If the angle becomes obtuse, the patency is maintained and a greater pressure and volume of the aortic blood passes into the pulmonary artery the wall of which, not intended for such pressure, may yield to form an aneurysm. The presence of these two associated lesions leads to diagnostic confusion and adds another argument in favor of surgical closure of the recognized patent ductus.

ROBERT BRIGLOW M.D.

Alexander J. and Byron, F. A.: Aortectomy for Thoracic Aneurysm. *J Am Med Ass* 944, 186 1939.

The authors successfully removed an aneurysm of the thoracic aorta measuring 11 by 8 cm. together with a 7.5 cm. length of the aorta. This is believed to be the first case of successful removal of an aneurysm of the thoracic or abdominal aorta or of successful ligation of the thoracic aorta. The patient was a white youth, aged nineteen whose symptoms and physical signs led to a provisional diagnosis of aortic coarctation on the basis of extrinsic pressure by a neoplasm (Fig. 1).

Thoracotomy was performed under intratracheal ether anesthesia and a sacular aneurysm of the upper descending aorta was exposed in the costovertebral gutter. The upper pole was 5 cm. inferior to the left subclavian artery and the attachment to the aorta was about 7.5 cm. long. The pulsations in the aorta above it were strong but those in the aorta below it were only questionably palpable. The aorta at its junction with the upper end of the aneurysm appeared to be slightly constricted. The subclavian internal mammary and upper intercostal arteries were greatly enlarged. As the thin-walled aneurysm was in danger of rupture at any time and as the collateral circulation appeared to be adequate, resection of the aneurysm was decided on. The aorta just below the origin of the left subclavian artery was ligated with a 1.3 cm. wide cotton tape, and a silk ligature was placed between the tape and the place where the aorta was to be divided. The aorta was similarly ligated 4 cm. below the aneurysm. Three pairs of greatly enlarged intercostal arteries emerging from the aneurysmal sac were ligated and the entire aneurysm-bearing segment of the aorta was removed. The divided ends of the aorta were oversewn with silk, and a pedicled flap

Fig. 1. Before and after resection of the aneurysm. Actually the aneurysm was 11 cm. long. Its attachment to the aorta was 7.5 cm. long.

of the posterior aneurysm wall was turned over the open end of the superior segment of the divided aorta and tacked to the aortic wall (Fig. 1).

The feet remained warm throughout the operation and afterward but there was a postoperative rise in blood pressure in the upper extremities. Acute cardiac decompensation occurred seventeen days after operation and receded rapidly under treatment. Up to three months after operation kidney function tests were consistently normal but there was persistent hypertension with retinal angiospasm, exudates, and hemorrhages. One year after operation the patient's activities were the same as before operation, and examination showed the acute process in the retinae to be at a standstill although the hypertension was still present. Because of the persistent hypertension and angiospasm the prognosis of the condition must be guarded.

This aneurysm probably arose in connection with an aortic coarctation, the presence of which is presumed because of hypertension, a well developed collateral circulation, notching of the ribs and the absence of pulsation of the aneurysm and of the aorta below it. This patient was unique in that all the factors essential to the success of the operation were present: his youth and good general health, the absence of syphilitic disease of the aorta, the presence of a well established collateral circulation, and the location of the aneurysm which permitted the placing of the proximal ligature on the aorta below the left subclavian artery.

JOHN L. LEXQUIST, M.D.

Scott, V.: Abdominal Aneurysms. *Am. J. Syph.* 1944, 28: 682.

In a series of 96 cases of abdominal aneurysm of the aorta or its main branches, 58.3 per cent were syphilitic, 20 per cent arteriosclerotic, and 18.8 per cent mycotic. In 43 of these cases the aneurysm involved a branch of the aorta. Of the latter cases 33 per cent were syphilitic and 18.6 per cent were arteriosclerotic, and in 41.9 per cent the aneurysm

was caused by bacterial agents. Multiple abdominal aneurysms were present in 18.7 per cent of this series and in 30 per cent arteriosclerosis was the causative agent. Aneurysms of the upper abdominal aorta, including those involving the celiac axis and superior mesenteric artery were most frequently syphilitic, while those of the lower abdominal aorta were either arteriosclerotic or bacterial. Arteriosclerotic aneurysms usually occurred in patients over fifty years of age and of the white race; they were predominantly males. Luetic aneurysms occurred mainly in the colored race.

The symptomatology of abdominal aneurysm is dependent upon its size and location. Pain, especially of the nocturnal type, was characteristic in the luetic group. Often it was associated with vertebral erosion. Arteriosclerotic aneurysms were asymptomatic in 80 per cent of the patients. In the mycotic type bacterial infection masked any aneurysmal symptoms. The presence of a pulsating expansile mass with palpable thrill and audible bruit was dependent on the size and location of the aneurysm. In 75 per cent of the luetic group the latter physical signs were detected. In a differential examination it must be remembered that neoplastic or inflammatory tumors close to large arteries may give similar findings. Furthermore intraluminal clotting may cause the thrill and bruit to disappear. The largest sized aneurysms were usually luetic, but in all groups the sacular variety predominated. Rupture of the aneurysm occurred frequently in from 39 to 41 per cent of the mycotic and luetic types—and hemorrhage extended commonly through the retroperitoneal tissues and less frequently into the peritoneal cavity.

Thirty-four per cent of the patients with luetic abdominal aneurysms also gave signs of aneurysmal involvement of the thoracic aorta. Erosion of the vertebra was common in the luetic aneurysms of the upper abdominal aorta. This was usually demonstrated by x-ray examination which also revealed calcium deposits in the vessel walls.

The prognosis of syphilitic abdominal aneurysm was found to be variable but poor. In 70 per cent of the patients death ensued within thirty-six months after the onset of symptoms and only 17 per cent lived more than five years.

As regards treatment, there has been little tendency to treat such lesions. However, Blakemore and Lord have recently offered a promising method of controlled electrothermic coagulation for aneurysms.

BLOOD; TRANSFUSION

Invernizzi, D. and Yannicelli, S.: Distribution of the Rh Factor in the Population of Montevideo (Distribucion del factor Rh en la poblacion de Montevideo) *Arch. surg. med.*, 1944, 5: 85

This article describes the first attempt at determining the frequency of the Rh factor in the blood of the population of Montevideo. The majority of the individuals examined were voluntary donors of blood in the Center for Blood and Plasma. Some determinations were made in the Maternity Hospital with the object of studying a case of fetal erythroblastosis which will be published elsewhere.

The anti-Rh sera used were from two sources. The first was obtained from a woman who gave birth to a child which died of fetal erythroblastosis. This serum contained an irregular agglutinin which was identified as anti Rh. The other was a human anti Rh serum given by the Rockefeller Foundation of New York.

The technique of the reaction is described. Among the 113 determinations, 92 or 81.4 per cent, were Rh-positive and 20 or 17.85 per cent, were Rh negative.

AUMERY G. MORAN, M.D.

Macklin, M. T.: The Diagnosis of Rh Incompatibility Especially by Microscopic Appearances; Its Relation to the Syndrome Formerly Diagnosed as Erythroblastosis. *J. Pediat.*, S. Louis, 1944, 5: 533

Erythroblastosis as originally defined indicates the presence of large numbers of nucleated red blood cells in fetal livers at a stage in development when erythropoiesis should largely be absent from the liver. This is evidenced by the presence in the circulating blood of the fetus or newborn infant, of immature red cells the type or quantity of which is not normal for that stage of development. Rh incompatibility is suggested as the term for the disease entity caused by a reaction between Rh antigens in the fetus and the specific antibodies in the maternal blood to combat them. This results in erythroblastosis due to hemolysis but many conditions other than those involving incompatible Rh factors in mother and fetus are factors in the production of erythroblastosis. The author outlines diagnostic criteria of Rh incompatibility. Many of the criteria said to be diagnostic of Rh incompatibility may be found in other conditions and may not always be found in Rh incompatibility.

In order to diagnose whether a fetus is suffering from Rh incompatibility it must be shown either (1) that the fetus possessed in its circulation antibodies against its own Rh positive cells, or (2) that the blood of the fetus and mother were of different Rh groups and that the fetal tissues showed departures from normal which were characteristic of the antigen-antibody reaction.

Probable Rh incompatibility can be diagnosed in the living infant when different Rh factors are demonstrable in mother and fetus, and an anemia, or jaundice, or both, unexplained by other conditions are present in the infant. The diagnosis is strengthened if other infants in the same family have suffered from fetal jaundice or from proved Rh incompatibility.

Probable Rh incompatibility can be diagnosed in the stillborn infant or in the infant after death when different Rh factors are present in mother and fetus, and when the fetal liver shows that hemolysis has taken place as evidenced by the presence of iron in the liver. This is determined by the Prussian blue technique.

Some of the criteria used for the diagnosis of Rh incompatibility are of value only when the fetus is full term or when the infant lives for several days. They are not of value on fetuses lost early in pregnancy. The iron test is of value in these early cases.

Iron is not normally stored in fetal livers in such form that it is demonstrable by the Prussian blue technique; therefore, iron as revealed by this test indicates excess blood destruction. One of the most frequent causes of such excess destruction is Rh incompatibility.

ERNEST E. ANDERSON, M.D.

Camponovo, L. E.: The Study of Oxalic Acid as a Hemostatic (Contribucion al estudio del acido oxalico como hemostatico) *Rev. As. med. argent.*, 1944, 38: 98.

The author reviews the work previously done on the use of oxalic acid as a hemostatic. Some investigators hold that it does act as a hemostatic, while others deny this property.

He reviews the physical properties of the acid, and its metabolism and pharmacology before he takes up the description of his experiments. A certain amount of this acid is found normally in the blood. The author gave it to dogs by intravenous injection in doses of 5, 10 and 20 mgm. The determinations of the coagulation time were made by the method of Lee and White. A control animal did not show any change in coagulation time in the various tests. Tests made ten minutes after the injection of oxalic acid showed lengthening of the coagulation time in some of the experiments, no change in some, and moderate shortening in others. The details of the results are given. Tests made twenty minutes or later after the injection showed shortening of the coagulation time, with the maximum shortening between fifty and seventy minutes after injection.

Oxalic acid was used clinically in 10 cases of hemorrhage in human subjects due to various causes.

The injections in these cases were made intramuscularly. The drug proved effective as a hemostatic, the maximum shortening of the coagulation time occurring one hour after the injection.

The exact manner in which oxalic acid acts in shortening the coagulation time is not known. Schumann suggests that it acts as a catalyzer which assists the action of the calcium, platelets, and tissue fluids in forming thrombin. Page, Russell, and Rosenthal think that it changes the surface tension of the membrane of the platelets and brings about the liberation of thromboplastic material in this way.

AUDREY G. MORGAN M.D.

Boyer E. H., Flippin, H., Verwey W. F. and Woodward, R.: The Effect of Para-Aminohippuric Acid on the Plasma Concentration of Penicillin. *In* *Man. J. Am. J. Dis.* 1944, 126, 1007.

The authors note that when sodium para-aminohippurate and penicillin are administered simultaneously the former compound competes with penicillin for the same renal tubular excretory mechanism. By doing so the rate of renal elimination of penicillin is much reduced which slows up considerably the rate of fall of the plasma concentration of the antibiotic agent. A combination of these agents was administered continuously to experimental animals without the production of the functional or histomorphological changes attributable to the two agents. Moreover it was shown that the acute toxicity of sodium para-aminohippurate was very low.

In view of the implications of the possible therapeutic efficacy of the combination, it was decided to obtain data on a few patients to determine whether the simultaneous administration of para-aminohippuric acid with penicillin produced an elevated plasma concentration of the antibiotic agent. A careful study of the patients for any untoward reactions was thereby permitted. The methods followed in the administration of penicillin to 9 patients are presented. The methods for the plasma assays of penicillin and of para-aminohippuric acid also are presented.

The results of the tests on these 9 patients are summarized in a tabulation. Examination of the table reveals that in every instance the administration of para-aminohippuric acid with penicillin caused at least a twofold increase in plasma concentration of the antibiotic agent. There was a definite relationship between the plasma concentration of para-aminohippuric acid within this range and the amount to which the penicillin level was elevated. There was no outstanding difference in response due to age, sex, or race.

The pharmacodynamic effects of sodium para-aminohippurate are considered in two categories: (1) those attending the injection of the priming doses, and (2) those occurring during or following the para-aminohippuric acid infusions. Only when para-aminohippuric acid was administered at room temperature was any reaction noted. The only noteworthy untoward effect which occurred follow-

ing the administration of certain of the priming doses of para-aminohippuric acid was a contraction of the smooth musculature of the large intestine and bladder unattended by pain or discomfort. The infusion of para-aminohippuric acid and penicillin continuously for twelve hours produced no discernible deleterious effects on the patients who manifested a number of unrelated disease entities.

The authors suggest that the plasma concentration of para-aminohippuric acid be checked frequently to make sure that the function of diseased kidneys is sufficient to allow excretion of the drug rapidly enough to prevent an excessive blood level of para-aminohippuric acid. Moreover the authors note that more effective plasma concentrations of penicillin were found to be present in patients who had known renal involvement. In the light of recent work, this can be interpreted as being due to renal damage which decreases the transport capacity of the tubular excretory mechanism.

HERBERT F. THURSTON M.D.

Opazo, V. Retinal Hemorrhage following Transfusion (Hemorragia retiniana post transfusional). *Bolet. Soc. Chilena Obst. Gyn.*, 1944, 9, 153.

Attention was first called to the complication of retinal hemorrhage following blood transfusion by Sallmann in 1935. Since then a number of cases of retinal hemorrhage and one of permanent and one of temporary blindness following transfusion have been reported.

The author reports a case in a woman of forty-nine who was to be operated on for ovarian cyst after previous treatment to improve her general condition. The circulatory system was normal. She was given three blood transfusions, and about three and one-half hours after the third transfusion retinal hemorrhage developed.

After a discussion of the cases reported the author concludes that this complication occurs only when there are predisposing causes such as long-continued anemia, and that it occurs most frequently when repeated transfusions have been given. He believes it is not a serious complication, although some students of the subject think it is.

AUDREY G. MORGAN M.D.

Koop, C. E.: The Use of a Specially Prepared Gelatin Solution as a Plasma Substitute. *Surg. Clin. N. America*, 1944, 24, 1300.

Koop holds that gelatin is the best of the plasma substitutes and that it is equal to plasma in the treatment of shock. It is remarkably nontoxic and nonantigenic. The gelatin solutions used were specially prepared from selected raw materials to the finished product in a plant designed especially to prepare gelatin for intravenous administration to patients. Colloidal solutions such as gelatin are offered not as substitutes for whole blood but rather as substitutes for plasma. Plasma is used chiefly for its coagulating function, its nutritional value, its aid in the defense against infection, and for the proper

ties associated with the colloidal osmotic pressure of its proteins. Whole blood is used more extensively than plasma for its antihemorrhagic and antibacterial properties. The chief use for which plasma is employed is for the colloidal osmotic pressure of the plasma proteins when the desired result is maintenance of an adequate blood volume and its many related physiological phenomena. It is for this particular purpose that gelatin solutions are used so efficiently.

The criteria for an ideal plasma substitute are the following:

1. **Physical properties.** An ideal plasma substitute should be stable, of low viscosity and have a high colloidal osmotic pressure and the colloidal particle size should be sufficiently large to cause it to be retained in the circulation long enough to be effective. Finally there should be no difficult problems with storage.

2. **Physiological properties.** It must be safe for injection in large quantities, and it should not interfere with blood coagulation, the defense against infection or tissue repair. It must be nontoxic.

3. **Immunological properties.** It should not be an antigen and it should have no natural sensitivity to similar substances such as foods or sera.

The gelatin solution which has been most satisfactory is one prepared by hydrolysis of alkali treated long bone collagen under controlled and standardized conditions. It is administered as a 6 per cent solution in physiological saline solution after autoclaving for twenty minutes. (This is the solution Knox P so referred to by the National Research Council in its report on Gelatin as a Plasma Substitute. *J. Am. M. Ass.*, 1944 125: 284.) This solution is preferred for the treatment of shock because its method of preparation produces the optimum molecular size of the gelatin, upon which its physiological action largely depends.

When gelatin solutions are subjected to high temperatures, such as those required in sterilization by autoclave, the long gelatin aggregate molecule is broken down to form a larger number of smaller molecular particles. Whereas the smaller molecules theoretically exert a higher oncotic pressure, they are excreted from the blood stream through the kidneys so rapidly that their effective oncotic pressure is short-lived and not of the sustained value of the larger molecules which actually exert a lower osmotic pressure. For this reason two factors are of importance in the manufacture of gelatin solutions for plasma substitute: the source of the gelatin and the method of preparation of the solutions. Bovine long bones are a better source of gelatin than skins, hides, or fish products because of their relative freedom from bacterial and fungus contamination and their uniformity of composition. Gelatin solutions for intravenous use should be prepared for that purpose and apart from the commercial manufacture of edible gelatin. Even the use of pure U.S.P. edible gelatin in the preparation of intravenous solutions may result in a pyrogenic product because of im-

purities that may render it unfit for parenteral use. There are several advantages in the preparation or processing of gelatin solutions. Whereas the preparation of plasma must be undertaken with the most rigid sterile technique, gelatin solutions, if prepared with reasonable cleanliness, can be thoroughly sterilized in the last step of manufacture by autoclaving and Seitz filtration. Gelatin solutions need not be refrigerated as fresh plasma must be, and they can be kept in a single container as compared with the two needed for hypophilled plasma. When the solution is prepared as a single dose package, no preservative need be added. This avoids the possible danger of chemical phlebitis due to preservatives. The great advantage of gelatin is that it is readily available at relatively low cost and that we are not dependent upon blood donations to obtain it. This is of special practical importance in localities and hospitals where plasma banks are not established.

Gelatin solutions are miscible with all of the usual intravenous solutions and can be administered by means of any of the "open" or closed methods. The open system, which is frequently used for transfusions of whole blood or plasma, has been satisfactory for use with gelatin. Unless heated, gelatin solutions of the type recommended are in the physical state of a gel at ordinary room temperature in the temperate zone. However because the gelation point is lower than the melting point, these solutions, once warmed remain fluid at room temperature unless exposed to a cold atmosphere such as that from an open window. Gelatin solutions kept in a warm closet at 37°C. are ready for immediate use. Inasmuch as there is a very slow deterioration, or shortening of aggregate molecular chains, such solutions should not be stored at 37°C. over a month. An alternate method of preparation is immersion of the gelatin bottle in a hot water bath until melting takes place. Minimal viscosity and hence greater speed of infusion is found at 50°C. The return to the gel state does not occur until ample time has passed for administration at ordinary room temperature. As with plasma or whole blood, it is advisable not to use needles of a size smaller than 19 gauge for gelatin infusions. In the treatment of shock during which it is occasionally of advantage to administer gelatin relatively rapidly an 18-gauge needle should be used. It has not been necessary in the cases treated to infuse gelatin under pressure, although there is no reason why such a method would be impractical because of any properties of gelatin. It is possible to administer a suspension of erythrocytes with gelatin. This is an inexpensive procedure in those places where erythrocyte suspensions are available without cost as a by-product in the preparation of plasma. One difficulty arises in the administration of gelatin-erythrocyte suspensions. Gelatin increases the sedimentation rate of erythrocytes, and thereby occasionally causes the needle to become plugged by the high concentration of cells in the dependent portion of the apparatus if some precaution is not taken. The addition of a 5

per cent dextrose solution in equal quantity facilitates the administration of gelatin and erythrocytes. A more complicated but certain method is to bubble oxygen through the mixture to keep the cells in uniform suspension. The size and frequency of infusion must be governed by the requirements of any given case. Gelatin infusions must be given with the same care as an infusion of plasma and may be given for similar indications.

The administration of single and repeated infusions of ossein gelatin has been accompanied by few local or general reactions. Venous thrombosis has occurred in less than 3 per cent of infusions. This was true even when phenyl mercuric borate was added to the gelatin as a preservative. No unusual difficulty has been encountered in local extravasations of gelatin solution from its accidental introduction subcutaneously. The use of hot wet dressings is of advantage in hastening the absorption of such collections.

THE CLINICAL USE OF GELATIN SOLUTIONS

Treatment of shock Experience in treating shock following burns, hemorrhage and trauma has demonstrated gelatin solutions to be effective. It is difficult in clinical practice to judge the comparative efficacy of a plasma substitute, as one is separated from the controlled conditions of the laboratory. Studies on volunteers bled into shocklike states while under observation on the ballistocardiograph have established the efficacy of gelatin in the treatment of hemorrhage on physiological grounds. As a routine in the treatment of shock an intravenous infusion of 6 per cent gelatin is started as soon as possible. Usually 500 cc. are sufficient to bring about a rise in blood pressure and pulse volume but occasionally more are required. It may be desirable to give another gelatin infusion several hours later or to give a whole blood transfusion. The rate of infusion is important in some cases of shock. It is customary to administer the solution as rapidly as it will flow by gravity through an 18 or 19 gauge needle. In cases of hidden hemorrhage an effort should be made to keep the patient out of shock but to maintain his blood pressure at a sufficiently low level, usually about 100 mm. of mercury systolic, to favor clot formation and to discourage brisk bleeding. One possible danger of administering large quantities of gelatin to such patients is that they may continue to bleed internally but fail to show a fall in blood pressure or an elevation in pulse because of the maintenance of blood volume. The severe anemia which may develop is detected only by the observation of pallor or a marked fall in hemoglobin or hematocrit reading.

Treatment of burns Gelatin has been used to some extent in the treatment of burns, but E. I. Evans has treated a comparatively large series of second-degree burns with gelatin with success comparable to that obtained with plasma. He believes that repeated infusions of 500 cc. of gelatin solution every four to six hours is a better practice than less

frequent larger infusions, and that after thirty-six or forty-eight hours whole blood is usually indicated. Because of the size and shape of the gelatin molecule it is likely that it is lost less readily from the surface of a burn than is plasma, although no accurate data are available. The probability of this phenomenon serves as a reminder however that while the blood volume and hematocrit reading might be maintained the plasma protein can leak out of the denuded area to produce a severe depletion of natural serum proteins. With our present knowledge it would seem advisable to give whole blood or plasma to the patient treated with gelatin who survives the shock phase of his burn. The use of gelatin solutions intravenously in no way alters the use of adequate local treatment to the burned area.

As a supportive measure in operative surgery In a patient about to undergo surgery under serial spinal anesthesia, a gelatin infusion before or during the procedure has very frequently prevented the expected fall in blood pressure. Especially in emergency surgery under any type of anesthesia, the use of gelatin infusion during an operation has aided many patients in coming through an otherwise difficult procedure without the added danger of an unstable pulse and falling blood pressure. On several occasions during emergency surgery when gelatin solutions were used the response of the patient was impressive.

Treatment of edema It is in this field especially where little is known about gelatin, that there is need for further investigation. Gelatin solutions have been effective chiefly in edema due to hypoproteinemia which may itself be due to many causes. The author has been successful at times in treating edema due to starvation liver cirrhosis, and nephrosis as well as several cases of terminal anasarca in lymphosarcoma and Hodgkin's disease. In the management of these problems, daily infusions of 500 cc. or 1000 cc. of a 6 per cent gelatin solution were given, with a close watch on the serum albumin concentration. The use of mercupurin in doses of 2 cc. after several gelatin infusions has resulted in greater diuresis in certain cases than either mercupurin or gelatin solutions alone. Because of the increase in blood volume which follows gelatin infusions, its use should be avoided in patients with edema of cardiac origin. The large molecular gelatin produces greater diuresis than the small. In several instances, administration of the small molecular gelatin has been followed by an increase in weight. The gelatin concentration of edema fluid has been found to be greater after infusion with the small molecular material than with large molecular gelatin. We have been asked if gelatin has an effect on pleural effusions or abdominal ascites. No such hope was entertained and no beneficial effect has been seen, although peripheral edema associated with either of these conditions may be benefited.

The chief precaution to be observed in the use of gelatin solutions is one suggested by the circulatory

changes after gelatin infusion. The 6 per cent gelatin solution has twice the oncotic pressure of plasma and, therefore, must be used with caution in patients of doubtful cardiac status. It should not be used at all in patients with any signs of cardiac failure, no matter how slight. As it has been shown the maximum blood volume increase occurs three hours after infusion and for that reason cardiac decompensation may occur some hours after the close of an otherwise uneventful gelatin infusion. Paradoxically the availability and low cost of gelatin solutions are in themselves sources of potential danger for without need of blood donors or the necessary formality of obtaining plasma from the plasma bank, the clinician has a large supply of a powerful agent ready for immediate and continued use. If the limitations of gelatin solution are kept in mind and it is used with the same judgment and precaution as plasma and for similar indications, it will prove an effective plasma substitute.

BENJAMIN GOLDMAN, M.D.

RETICULOENDOTHELIAL SYSTEM

Fotheringham, W. T. and Sugasti, J. A.: The Importance of Roentgenology in the Diagnosis of Traumatic Ruptures of the Spleen (Importancia de la radiología en el diagnóstico de las rupturas traumáticas del bazo). *Rev. As. méd. argent.*, 1944, 58, 9, 3.

Traumatic ruptures of the spleen without an open wound of the abdomen are extremely rare. Only 8 have been seen among 3,500 admissions to the Emergency Surgical Service of the Public Welfare Hospital of Rosario.

Unless the hemorrhage is very profuse and floods the peritoneum at once there is generally a latent

period during which the clinical symptoms are slight and indefinite. It is during this period that diagnosis should be made in order that surgical treatment can be effective. The only means of making an absolutely certain diagnosis is by roentgen examination. If the possibility of rupture of the spleen is suggested by pain in the left hypochondrium irradiating to the shoulder of the same side a simple screen examination without contrast should first be made with the patient standing. This will show an abnormal opacity at the bed of the spleen which pushes the left diaphragm up and renders it immobile. The great tuberosity of the stomach is pushed toward the midline and the air chamber is reduced in size. The splenic angle of the colon is pushed downward and inward. An examination with contrast medium is then made which confirms the changes in the air chamber of the stomach and shows others in its middle part, a characteristic image.

The diagnosis can be confirmed absolutely by the injection of about 1,000 cc. of air followed by screen examination. This shows the spleen in the greatest detail, particularly its upper pole. Its base passes into an opacity which shows a fluid level extending from the lateral surface of the spleen to the ribs. Sometimes there are other fluid levels in the right hypochondrium. If the patient is moved slightly there is an unmistakable wave in the fluid level. These changes should be recorded on roentgenograms.

The authors describe 6 cases in which they made the diagnosis by means of roentgen examination and present the roentgenograms. In 3 other cases in which pain in the left hypochondrium suggested traumatic rupture of the spleen roentgen examination proved that it did not exist.

AUSTIN G. MORROW, M.D.

SURGICAL TECHNIQUE

WAR SURGERY

Moore, T : Underwater Blast Injuries of the Abdomen. *Brit. M J* 1944, 2 626

The basic mechanism of underwater blast injuries to the abdomen is still uncertain. This article is based on the treatment of 18 patients, 9 of whom were subjected to operation. There were also 22 other patients who were examined and questioned and kept under observation after having been operated upon elsewhere.

In underwater blasts there is no after wave of negative pressure, thus the abdomen is affected more than the thoracic cavity. The shock of the explosion on the abdomen may be described as being like a severe kick or a viselike tightening as though the abdominal contents were forced up through the body into the head or as if a giant hand were squeezing the body from the waist downward. Many victims have the sensation of having the legs shot away. Several patients have had temporary paraplegia. None of the patients in the group described complained of pain in the testes.

Following these painful symptoms the patients managed to swim but after they had been picked up by another vessel they found they could not straighten themselves up or walk because of abdominal pain. After rescue there may be an urgent desire to defecate a blood-containing stool. Vomiting is a very common symptom.

Clinically these patients show all the signs and symptoms of a generalized severe abdominal blow. Many die at once or shortly after their injuries from shock and hemorrhage. The clinical picture in those rescued varied according to the time which had elapsed since the injury, and the extent of the injury. The more severe the injury the more severe the abdominal pain, vomiting and shock.

The most important early factor in the diagnosis is to know whether intestinal perforation has occurred. The greatest attention must be paid to the local abdominal signs, the most important of which are tenderness and rigidity. Intestinal perforation may be stimulated by intraperitoneal hemorrhage and by injury to the lungs.

The author places great reliance on the observation that if rigidity is caused by peritonitis due to perforation the abdomen does not relax during expiration. Late perforations of the intestine may occur.

The most important lesions are hemorrhage and perforation. Hemorrhages may be of the scattered pinpoint type, the linear subperitoneal, or the massive, irregular subperitoneal type. Perforations were found in the ileum and in the ascending and pelvic colon. Perforations varied from the size of a pin point to 3 cm. in diameter. Frequently there is only one perforation but at times several may be found.

Various other hemorrhages and injuries to the internal organs are described. Gas-containing abdominal viscera are most commonly and markedly affected.

Any one within 200 yards of the explosion is in danger and those facing the explosion are usually more seriously injured than those with their backs to it. Distance is the best safeguard against injury and the safest position appears to be floating on the back.

Treatment consists of rest, warmth, morphine and intravenous infusions of blood or plasma. Mask administration of oxygen is used for patients with chest lesions.

Late perforation must always be considered and appropriate measures taken. In cases of perforation operation is performed as soon as the patient is fit for surgery. Spinal analgesia is suitable if shock has been overcome. Intravenous administration of pentothal sodium combined with local block are useful in these cases. One of the sulfonamides is used before the abdomen is closed. Ordinary suture of the colon is carried out and the peritoneal cavity is drained. Continuous gastric aspiration and the intravenous administration of fluid and sulfonamides are extremely important postoperatively.

Nine of the 18 personal cases were submitted to operation. Perforations were found in 8 of the patients. There were 2 deaths and in these cases perforations of the intestinal tract and blast lung were found. The mortality among the operative cases was 22 per cent.

The postoperative complications were peritonitis, purulent bronchitis and acute obstruction of the small intestine. Two of the patients who had been treated elsewhere previously for perforation of the bowel, subsequently developed intraperitoneal abscess. Another patient developed a subphrenic abscess.

RICHARD J. BENNETT JR., M.D.

Mitchell, G. A. G. : Infection in War Wounds. *J. R. Army M. Corps* 1944, 85 225

Mitchell attributes the high incidence of infected wounds in military as compared with civilian life to (1) the severity of the average battle wound, (2) the proportion of open or closed fractures and joint injuries, and the degree of bone and soft tissue damage, (3) the soiled character of the soldier's skin and clothing, (4) penetration and perforation of the body cavities, (5) the presence of foreign bodies and their irritant nature, (6) the circumstance of exposure to excessive heat or cold, battle strains, and lack of food and drink, (7) the circumstance of immediate treatment on the battlefield, (8) the necessity of transporting many hundreds of miles over difficult country before the wounded reach hospitals, and delays in getting definitive treatment, (9) the difficulty of maintenance of strict asepsis under battlefield

conditions, and the risk of cross infection and (10) infection from vectors such as flies.

Bacterial infection was of the mixed type in all except 6 of the cases observed the most common combined infection being caused by streptococci and staphylococci, although other organisms were often present with these in the same wound.

Streptococcal infections usually proved more troublesome in the earlier stages and were more liable to produce signs of general intoxication, while staphylococci were more persistent and difficult to eradicate, and were present in a high proportion of the truly chronic wounds.

The bacteriologist can provide invaluable help yet too much emphasis must not be laid on the laboratory findings and prevent definitive treatment.

The cautious assessment of laboratory reports is especially necessary when the clostridia group are considered. In the orthopedic cases, these organisms were present in 25 per cent of the wounds, but only 1 patient had true gas gangrene and he might have escaped this complication if his grossly lacerated and contaminated leg had not been encased in an unsplit, unpadded plaster with consequent swelling and interference with the circulation. The presence of clostridia organisms should never by itself lead to a diagnosis of gas gangrene. The diagnosis can be made with certainty only on the clinical appearance and examination of excised portions of the affected muscle.

Infected war wounds, like any others, may become chronic. Every general hospital with many casualties always has its quota of chronic cases. Figures show that approximately 33 per cent of the wounds at the author's hospital were still unhealed after two months, but in three months the number had fallen to 10 per cent largely because the removal of sequestra in 7 cases led to healing of persistent sinuses. The wounds slowest to heal were the sequel of mine explosions, and most of those were heavily contaminated and contained multiple foreign bodies.

The causes of chronicity in war wounds are many and various, but possibly the two chief ones are the gross and extensive nature of the original injury and the fact that infection is often well established before the surgeon has a chance to prevent it.

There are other factors also. The area of skin loss may be so great that healing by natural processes must inevitably be a lengthy process. The patient may be debilitated and his resistance undermined by strain, exhaustion, loss of blood, or a virulent infection. He may have suffered from lack of proper food and water, and in a few cases there may be some constitutional disease, such as nephritis, which reacts unfavorably on the reparative powers.

STEPHEN A. ZIDMAN, M.D.

Neel, H. B., and Cole, J. P.: Gas Gangrene in Amphibious Warfare in the Pacific Area. *Am J Surg* 94:4, 66-90.

In 984 consecutive fresh battle casualties there were 7 cases of gas gangrene. In all the cases a

gram-positive bacillus, morphologically and culturally identified as the clostridium welchii, was found. The incubation period varied from one and one half to five days. The average time that elapsed between the injury and the appearance of the symptoms was two and thirty five hundredths days.

The lower extremity was the site of the infection in 5 cases, and the upper extremity was involved in 2 cases. The wound in each case was large, deep, and irregular and it involved muscle. In 5 cases, fractures were present, and in 1 case amputation had been done previously.

In nearly all of the cases, pain was the initial symptom. Two patients were delirious on admission to the hospital. Local swelling, discoloration, crepitus, and a foul odor are the early diagnostic signs. Evidence of toxicity appears late in the course of the disease. A persistent elevation of the pulse rate was present. The temperature was not a reliable index to the severity and extent of the infectious process. A low erythrocyte count and a low hemoglobin content were the most striking laboratory findings. In 1 case the diagnosis was confirmed by x-ray examination.

The treatment, both prophylactic and therapeutic, is primarily surgical. Early care of wounds and excision of devitalized tissue may reduce the incidence of gas gangrene. In 1 case excision of the wound gave satisfactory results. In the remaining 6 cases, amputation was necessary. Wounds should be left open, and vaseline gauze should be placed in them. Spraying of the stump with microcrystalline sulfathiazole was the practice in the hospital ship.

In patients with wounds of the extremities which are obscured by casts, early diagnosis of gas gangrene is difficult. The patient should be questioned frequently concerning the presence of pain. The cast should be examined for the characteristic odor of gas gangrene swelling below the cast should arouse suspicion.

Multiple transfusions of whole blood were found to be the most valuable single adjunct to surgery.

Two of the 7 patients died.

SAMUEL KARR, M.D.

Hutchinson, D. F. and Chapman, H. R.: The Evacuation of Casualties from a Normandy Beach. *J R Army M Corps* 94:4, 83-90.

This article narrates in detail the plan employed in the evacuation, transportation, and disposition of casualties from the Normandy beaches during the initial stages of the invasion assault. This consisted in evacuation of all casualties by sea from each of the 3 British sectors. An organization known as the Casualty Evacuation Point was set up on or near to the beach. It collected the casualties in D.U.K.W.'s (ducks), and transported them to Landing Ship Tanks (LST) anchored at sea.

On D+1 day the LST was beached and the casualties were loaded aboard after the ship had discharged its cargo of men and supplies. Sixty per cent of the casualties were evacuated in this manner.

each LST accommodated 144 bed patients and walking patients and evacuation fell into 2 categories according to the water tide—the low tide, when loading was done directly onto an LST and the high tide, when it was done onto a hospital ship anchored from 3 to 5 miles out from shore on the carrier's water ambulance or a Landing Ship Tank from a harbor 2 miles from the CEP. Every patient sent to the Casualty Evacuation Station was seen by a medical officer on arrival, was given a meal or some tea, had his dressings adjusted and was given whatever adjustment treatment might be required, also cigarettes and sweets. Here he could rest until evacuation was feasible, during which time his documents were checked.

The activity which received these patients was well organized: there were 3 medical officers in the Reception Center on duty during the day and night.

STEPHEN A. ZILMAN, M.D.

Gray R. O. and Mossendow N. A.: *Embarkation of Casualties from a Beach Head*. *J R Army Med Corps* 1944 83 215

This article discussed the evacuation of casualties from a beach-head, describing in detail the various methods employed. The plan of evacuation consists in using a Casualty Embarkation Point on the beach which collects the casualties and disposes of them principally by dispatching them to hospital craft. There are 2 types, the hospital ships and the hospital carriers. The latter are smaller and intended for short voyages only; consequently they have a specialized staff than the hospital ships. Each of the vessels serve several beach sectors and are supplied by Landing Ship Tanks (LST) water ambulances (usually 6 in number) from the hospital ship (LST), Landing Craft Tanks (LCT) with a capacity of 100 stretchers and 100 sitting patients, Landing Ship Infantry (LSI) with a capacity of 40 stretcher and 60 sitting patients, motor launches carrying 14 stretcher and 30 sitting patients, and DUKWs, which amphibious craft carrying 9 stretcher patients. When landing strips could be established evacuation by air was also employed; however certain serious patients for whom air travel was considered were denied this form of transportation. These were patients suffering from shock, abdominal and thoracic wounds, acute abdominal conditions, severe hemorrhage (including hemoptysis and atelectasis), gas gangrene, chemical gases, lobar pneumonia, pneumothorax, angina pectoris, coronary occlusion (during first month of condition) and lengths (during period of increased intracranial pressure).

Gray J. H.: *Reception and Evacuation: Notes on Administrative Problems Arising in a Large General Hospital (1,500 Beds) Acting as a Casualty Clearing Station*. *J R Army Med Corps* 1944 83 220.

This article describes the administrative problems which arose during the time in which the unit in

question functioned as a general hospital although its staff was limited to that of a casualty-clearing station. The clerical staff worked in a twelve hour shifts although these were stretched on many occasions to shifts of fourteen or fifteen hours duration.

The cases were received in a Reception Tent where documentation, sorting of patients, and exchanges of equipment were done. A convoy of 200 could be cleared in this manner within two hours.

After the convoy had been admitted the index cards were sorted and filed alphabetically.

When a patient was ready for evacuation a form was filled out; urgent cases were indicated with a priority label, also those requiring special handling, such as air patients and those with maxillofacial and head injuries. Clean x-ray films were included among the transporting records. The patients were then placed on evacuation vehicles, motor car or train ambulances, planes, or other conveyances, at which time all items were checked.

This system of recording by index cards has proved of inestimable value and was arrived at through trial and error. It has been modified according to circumstances but its value is worth the extra trouble entailed.

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Hamilton H. H., Custer B. S. and Kellner A.: *Pilonidal Cyst; An Analysis of 132 Consecutive Cases*. *Y England J Med* 1944 231 757

This analysis of 132 cases of pilonidal cyst calls attention to a method of preoperative grading which proved helpful in determining those cases suitable for primary closure. The preoperative classification of cases was as follows:

Grade 1: On examination the patient presents a sinus or sinuses and a palpable tumor but there is no history of inflammation or discharge.

Grade 2: The patient presents a history of discharge and recurrent local tenderness and swelling but not within the eight weeks prior to examination.

Grade 3: The patient presents a history of recurrent discharge or previous abscess formation requiring drainage.

Grade 4: The patient presents acute suppuration and abscess formation.

The series was thus divided as: grade 1, 45 cases; grade 2, 24 cases; grade 3, 45 cases; grade 4, 9 cases; and ungraded, 9 cases, of which 4 did not come to surgery and the remaining 5 were treated by excision and packing.

Excision and primary closure were done in 43 grade 1 cases, with 1 failure (2 per cent); in 20 grade 2 cases, with 3 failures (15 per cent); in 19 grade 3 cases, with 10 failures (53 per cent), and in none of the grade 4 cases. Failure is defined as any primary closure that requires reopening or that on follow up examination shows tissue breakdown or evidence of recurrence. The procedure of Ferguson and McCreay with minor modifications was followed.

In 82 cases treated by primary closure including the failures, the average time from operation to return to duty was twenty five days. Excision and packing was done in 24 of the first 66 cases, and the average time of hospitalization was sixty two days. Only 4 of the remaining 62 cases received this type of management, and the period of hospitalization averaged one hundred and two days. This procedure has been supplanted almost entirely by that of partial closure.

The technique of partial closure used by these authors was that of MacFee. This type of management was used in 21 cases, in 9 of which the cysts were of grade 3, in 1 the cyst was of grade 4, and in 1 of grade 1, this cyst being too large for complete closure. The average period of time from operation to return of the patient to duty was forty five days.

The procedure of incision and drainage was limited to 7 cases of gross suppuration and abscess formation. Incision and drainage at the outset and careful use of cauterizing agents effects a cure in simple types of abscesses. Care is taken to excise the fistulous tracts at the time of operation, and the wound is loosely packed with sulfanilamide gauze for one week. After this, the wound is treated daily with Carnoy's solution and saline solution until a clean granulating surface is presented. These patients were discharged to duty as healed in an average of twenty-seven days after operation.

It is concluded that grade 1 and grade 2 cysts may be satisfactorily closed by the modified Ferguson technique, with only rare failures and recurrences. Grade 3 cysts should not be closed primarily since failure occurred in 53 per cent in the cases so treated. The average hospital stay of the 128 patients operated upon for all grades of pilonidal cyst (from date of operation to complete healing and return to duty) was thirty five days. JONES L. LUDGIST M.D.

Karpovich, P. V., Starr, M. P., and Weiss, R. A.: Physical Fitness Tests for Convalescents. *J. Am. Med. Ass.*, 1944, 76: 873.

From an analysis of data presented it was found that three days after an acute fever of two and a half days duration an IAF cadet can pass a physical fitness test equivalent to walking up to a height of 20 feet and down again in thirty seconds (approximately to the third floor of an average building). One and a half additional days after fever the convalescent cadet can pass a physical fitness test equivalent to climbing up 100 feet and coming down in five minutes (approximately to the twenty first floor). After three more days he can make a score of 75 on the Harvard test for discharge to full military duty. The use of the Harvard test score of 75 is reliable for discharge to full duty since all of 271 cadets were able to carry on without relapse. Testing and participation in the physical training of the convalescent training program reduced hospitalization somewhat, definitely did not prolong illness, and insured adequate physical fitness for return to full military duty. From a small number of cases results

suggest that sedimentation rate (Westergren method) of the order of 24 to 35 mm. is not a contraindication to full participation in the hospital physical training program.

The clinical physical tests described in this article were used to assist medical officers in classifying IAF cadets convalescing from acute uncomplicated upper respiratory diseases for participation in a gradual physical training program. Participation in the physical training program resulted in a sufficiently high degree of physical fitness for the return of the subjects directly to full military duty when discharged from the hospital. J. M. MOON, M.D.

Brunschwig, A. and Nichols, S.: The Retention of Intravenously Infused Gelatin. *Surgery* 1944, 16: 9-13.

In recent years parenteral injection of nitrogenous nutriment has become feasible by virtue of the development of casein digests suitable for intravenous injection. Evidence has also been presented in support of the view that protein molecules (homologous plasma proteins) injected intravenously might be utilized for nutrition. The use of "complete" foreign proteins would not seem possible in view of their antigenic properties. However certain samples of gelatin have recently been found to be suitable for intravenous injection in that after their administration no immediate reactions were produced (except in isolated instances and these were not serious), sensitization did not develop and no later toxic effects were manifested. Gelatin, however, is an incomplete protein in that it lacks a number of the essential amino acids. As the sole source of protein in the diet it will not permit normal growth and development of experimental animals.

In view of the tolerance of human patients to repeated intravenous injections of gelatin and evidence that some of it is metabolized studies were carried out by the authors in a series of 23 patients to determine how much of this material is excreted in the urine under the usual conditions of intravenous clinical administration. This question is of obvious importance because if most of the injected material is excreted unchanged in the urine, little opportunity for utilization will be afforded.

Twenty three patients with various conditions received one or repeated daily intravenous injections of gelatin. In some instances the injections were made in the immediate postoperative period and the studies were carried out when the patient was receiving almost nothing by mouth. In others, the studies were carried out while the patient was partaking of the usual hospital diet.

As a result of their observations the authors present evidence to indicate that from 40 to 43 per cent of the gelatin injected intravenously in man as an 8 per cent solution in physiological saline solution is retained, as only from 60 to 57 per cent is recovered in the urine. The relative amount of gelatin retained is approximately the same whether 1 or 5 daily injections are made. Thus, the intravenous

Injection of gelatin constitutes one method by which antigenous material may be administered to the organism.

It is not to be inferred that these studies are regarded as final evidence to justify the assumption that gelatin given intravenously is a protein food. Evidence of appreciable utilization has not yet been presented. Emphasis is placed only on the fact that protein in the form of gelatin may be administered to the organism with the retention of appreciable quantities of the gelatin by the organism.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Fleming, A., Young, M. Y., Suchet J. and Rowe, A. J. E.: The Penicillin Content of the Blood Serum after Various Doses of Penicillin Given by Various Routes. *Lancet* Lond., 1944, 247: 681

Penicillin appears in the blood within a few minutes after an intramuscular or subcutaneous injection. From the point of view of getting the drug into the circulation, therefore, there is little to be gained by intravenous administration. Also the rapid rate of its disappearance from the blood is not markedly altered, whether the injections are given intravenously or intramuscularly.

The time at which measurable penicillin disappears from the blood is somewhat as follows:

Intramuscular dose	Time of disappearance
15,000 units.	2 to 3
30,000 units.	3
15,000 units.	4
30,000 units.	4 to 5
100,000 units.	5 to 6

The maximum titer obtained in the blood after the injection of 15,000 units is necessarily much less than after the injection of 100,000 units; therefore if the interval between injections is the same the larger the dose the higher will be the average penicillin content of the blood. When single injections are used, however, a continuous bacteriostatic power can be obtained in the blood much more economically by the use of smaller doses. Six doses of 15,000 units given every two hours will certainly maintain a bacteriostatic power in the blood for twelve hours, whereas 100,000 units in a single dose will last only from five to six hours. However, there are times when injections cannot be given frequently in such cases, the larger dose and less frequent injection are advantageous. There are times also when it is desirable to have a high concentration in the blood for only a few hours. If, for example, it is necessary to operate through septic tissues, a dose of 100,000 units given fifteen minutes before operation provides a high penicillin content throughout the operation and for an hour or two afterward, which seems to prevent any generalization or spread of the infection.

In hospitals, the most economical method of administering penicillin is by the continuous intramus-

cular drip. Even with a dosage of 60,000 units in twenty-four hours the blood serum is rendered bacteriostatic, and with increased dosage it becomes much more highly bacteriostatic.

As yet, no decision can be made as to whether it is better to maintain a constant low level of penicillin in the blood or to have a very high level for a short time after an injection, followed by a period of very low level before the next injection. Clinically both systems work excellently.

SAMUEL KAHN, M.D.

Myers, R. S., Aldrich, R. H., Howard, R. W., and Walsh, R. A.: The Use of Gauze Inoculated with *Penicillium Notatum* or Impregnated with Crude Penicillin in the Treatment of Surface Infections. *N. England J. M.*, 1944, 231: 761

In order to evaluate the use of gauze inoculated with *penicillium notatum* pieces of 28-by 24 mesh absorbent gauze were folded to form eight thick masses, cut circularly placed in clean Petri dishes and sterilized in a hot air oven for one hour at a temperature of 400° F. Five hundred cubic centimeters of distilled water were placed in an Erlenmeyer flask, to which was added 6 gm. of dehydrated yeast and 12 cc. of glycine. A separate mixture of 12 gm. of lactose, 12 gm. of cornstarch, and 30 cc. of cold distilled water was added. The contents of the flask was stirred well, and boiled for twenty minutes over a low flame. The Petri dishes and culture medium were cooled, and about 60 cc. of the medium were poured into each dish. A bit of the stock culture of *penicillium notatum* was then transferred to the plate with a flamed platinum loop. The dishes were placed in an incubator at a temperature of 23° C. The penicillin secreted during the growth process was deposited on the under surface of the gauze. Its concentration reached a maximum in twelve days and then rapidly retrogressed.

The plates containing the impregnated gauze maintained their potency for about two weeks when kept at a temperature of 5° C. or lower, and the crude penicillin liquor could be kept for about four weeks at a temperature of 5° C. without any appreciable loss in titer.

All cultures were insured against contamination. Before the dressings were applied the lesions were prepared by cleansing them with an aqueous cationic detergent or with hydrogen peroxide. Gauze pads inoculated with mold or impregnated with crude penicillin liquor were then applied and held in place by adhesive tape or bandages.

Several cases of uterine cervicitis were treated also. In these, a pad of the mold inoculated gauze or of gauze impregnated with crude penicillin was applied directly to the cervix. The dressing was held in place by a vaginal tampon for a period of thirty-six hours. With the exception of those on the uterine cervix, the dressings were renewed at intervals varying from one to four days. All of the patients were ambulatory which made it difficult to change the dressings more frequently.

Forty seven cases of surface infection were treated. Healing occurred in 25 and improvement was noted in 13 during treatment. The types of cases included leg ulcer chronic endocervicitis pilonidal sinus wound, mastectomy wound carbuncle burn of the neck, peroneal wound, and ulcerative stomatitis.

Chronic or mixed infections did not respond so well as did acute infections, or infections of but one strain of a penicillin sensitive organism.

Because of the difficulties associated with the preparation of crude penicillin and mold inoculated gauze, the authors advise that only purified penicillin should be employed for the treatment of cases of surface infection.

STEFAN A. ZIMAN, M.D.

Fauley, G. B., Duggan, T. L., Stormont, R. T., and Pfeiffer, C. C.: The Use of Penicillin in the Treatment of Peritonitis. *J Am M Ass* 1944 76: 13

Since peritonitis causes 92 per cent of all deaths in hospital patients admitted with a diagnosis of acute appendicitis, and it is also a frequent cause of death in ruptured peptic ulcer and penetrating abdominal wounds, the authors have prepared a controlled experimental study to ascertain the effectiveness of penicillin administration in controlling fulminating diffuse peritonitis.

They produced peritonitis in dogs by occluding the blood supply of the appendix by means of ligation of the mesenteric vessels and also of the base of the appendix and then giving 50 cc. of castor oil with the stomach tube. This type of peritonitis, with a bacteriological flora quite similar to peritonitis in man, has a mortality of approximately 100 per cent.

The authors picked dogs at random and divided them into three groups. The first served as a control. The second group, given the same supportive therapy as the first, was also given intramuscular penicillin therapy beginning one hour postoperatively and continuing every four hours until recovery ensued. The third group was treated similarly except that the penicillin therapy was not started until twenty-four hours after operation.

The clinical symptoms following the induced gangrene of the appendix in the dog are similar to those observed in appendicitis in man. In the control group 25 of 27 dogs (92.6 per cent) died of fulminating diffuse peritonitis in an average of fifty-seven hours. In the second group (penicillin starting one hour postoperatively) all 20 animals survived and at autopsy on the twenty-first day after operation no evidence of generalized peritonitis was present. The dosages used were 100 Oxford units per pound given intramuscularly every four hours to the first 3 dogs. Because of their critical clinical condition the rest of these animals received 150 Oxford units per pound every four hours for the first thirty-six or forty hours, then the dose was decreased to 5,000 units every four hours for two or three days, then to a total of 5,000 units every eight hours for two or three days. Twenty-eight dogs which developed the

operative complication of an internal fecal fistula died under penicillin therapy and were not included in these figures.

In order to ascertain the effectiveness of penicillin after the infection was well established, in the third group treatment was delayed until twelve hours after operation when definite abdominal rigidity was present. Penicillin was given as outlined for the second group with the result that 4 of 19 animals died a mortality of 21 per cent. The authors believe that large initial doses of penicillin possibly could have prevented these deaths.

The authors believe that since adequate penicillin doses given early are remarkably effective in the control of experimental peritonitis in dogs, it is reasonable to assume that the similar peritonitis in man due to appendiceal rupture will be favorably affected by adequate penicillin therapy. The longer the penicillin therapy is delayed the less favorable the results will be and the larger the dosages should be. Since relatively large doses of penicillin with regard to the body weight were used in these experiments, the authors believe that initial doses of 22,500 units per hour or about one-half million units per day would be necessary for a man weighing 150 pounds. As no toxic symptoms were displayed in this experiment and no serious symptoms have been described after massive doses in man, it would appear that large doses of penicillin are innocuous especially in relation to the critical nature of fulminating diffuse peritonitis.

In acute appendicitis the authors do not consider penicillin a substitute for early surgery based on sound surgical judgment, but they believe that its use may be indicated in such instances as (a) operations in which peritonitis is encountered or localized abscesses have been broken into, (b) operations on the large bowel or intestines when some sepsis occurs, (c) following gunshot or traumatic injuries to the abdomen, or (d) aboard small ships or submarines and at isolated posts where adequate surgery is not available.

ROBERT BLASLOW, M.D.

Burnett, W. E., Rosemond, G. P. and Caswell, H. T.: The Use of the "Sump Drain in Peritoneal Infection. *Surg Clin. America*, 1944 24: 36

The objectives of surgical drainage are as follows:

1. To remove exudate which may contain harmful toxins, necrotic tissue or living bacteria, or may cause mechanical interference with physiologic functions.

2. To allow ventilation and/or irrigation for combating anaerobes.

3. To produce by adhesions a limited space through which infectious material can be channeled at a subsequent time.

4. To indicate the type of exudate (blood, bile and so forth) from a hidden source.

5. To avoid the accumulation of exudate in an unavoidable or potential dead space (in amputations of the breast, extremities).

Fig. 1. A sump drain being used in generalized peritonitis. Note the exudate present in the bottle which has accumulated in eight hours. The abdominal dressing has not been changed in three days and is practically unsoiled. In actual practice the bottle and motor are on the floor.

Although only vaguely suspected at first, these principles have influenced doctors to utilize drainage for peritonitis since the infancy of surgery. Unfortunately the same protective process of adherence and loculation which surrounds and incarcerates contaminated areas tends to defeat drainage by walling off into many compartments the irritated peritoneal cavity. Thus, a drain consisting of an irritant foreign material was even more quickly sealed off from the remainder of the cavity often in a few hours.

Drainage in peritonitis is helpful in proportion to its efficiency. Gauze wicks tend to block drainage unless the exudate is thin, and cause early firm adhesions. Rubber of various compositions, is irritant and similarly is soon isolated. Drainage with such materials is of short duration; profuse amounts of exudate appearing for only a few hours. This has led to the search for less irritant materials which will not cause such rapid isolation.

In 1936 W. W. Babcock began seeking a drain of less irritant character which would increase the efficiency of drainage, more nearly approach the theoretical objective of the method and would be less likely to cause dense insulating adhesions. First glass, and later stainless steel fenestrated tubes were tried alone without gauze or other material about them. Inside each was a proportionately smaller tube, rubber at first, then stainless steel, connected to a motor-driven pump for constant aspiration of the pus which accumulated in these larger tubes, on the principle of a sump and this name was adopted for them.

In the treatment of peritonitis large quantities of exudate were withdrawn by this method in spite of operative aspiration. As much as from 100 to 200 cc. in each twenty-four hours for the first day or two has

been recorded. Often fairly large amounts continue for three or four days. Instead of becoming thicker and more malodorous, as seen with older types of drains, the material soon changes from purulent to serous, the odor disappears with varying rapidity and the serous fluid quickly diminishes in volume. This indicates absence of isolation and continued procurement of exudate as it forms. On several occasions the drains have been removed in two or three days because the patient's condition was excellent, peristalsis had returned, the graphic sheet was practically normal and only a little serous drainage was obtainable.

In addition to the important factors of decreased mortality and morbidity according to the authors tabulated experience in 96 cases other advantages of sump drainage are:

- 1 Removal of pus by positive means from the bottom of cavities instead of puddling and overflow from accumulation and body or intestinal movements as obtains with other methods. Thus even large but localized abscesses are more rapidly healed.

- 2 Frequent change of the small dressing is usually not required.

- 3 Ventilation and more adequate drainage decreases odor which is an important esthetic factor to many patients.

- 4 Pus is collected in a bottle with or without deodorant or antiseptic for easy disposal instead of on the dressings, clothing, and bedding for general contamination of the patient and attendants.

- 5 Postoperative hernia is much less likely — 1 or 2 small hernias were discovered at reoperation for appendectomy although they were not demonstrable before incision.

- 6 Postoperative obstruction is less likely. Two of the 62 patients, or 3.2 per cent, were submitted to

Fig. 2. Diagram of the sump drain. Note impossibility of direct suction on bowel or omentum provided there is a free airway between the inner and outer tubes. Note fish-mouth end of inner tube to avoid sealing.

ileostomy on the fifth postoperative day because of continued marked distention, but both had remained very septic and febrile, and the one on whom an additional blood count was taken showed continued leucocytosis. Both cases were interpreted as inflammatory rather than obstructive ileus, and both patients slowly recovered after ileostomy. Even when the condition is construed as being mechanical obstruction, its occurrence in 3.3 per cent of the cases compares favorably with the quoted statistics of 10 per cent and 7.4 per cent.

7 Postoperative secondary abscesses are rare. The one peritoneal abscess medial to the incision and two pelvic abscesses observed in these 62 patients occurred before the location of the drain was changed from right lower quadrant to the depths of the pelvis. Since this change, there has been no pelvic abscess formation.

In the extremely ill patients with diffuse peritonitis, shock is treated with plasma, blood, fluids, and adrenocortin. Without removal of the patient from bed an anesthetic is injected in the right lower quadrant for a 3-cm. muscle-splitting incision. Through this a long sump drain is gently inserted into the pelvis, being guided into the cul-de-sac by a finger inserted into the rectum. The sterile assistant can then anchor the drain to the skin with wire suture. No other sutures are needed. A modified Ochsen treatment including constant gastric or intestinal suction fluids, nutrition and blood (given parenterally) is applied. Sulfonamides may be used systemically or omitted. Appendectomy can be done when the patient has recovered sufficiently but not less than a week should elapse. For the average moder-

ately ill patient, appendectomy is done under spinal anesthesia through a small muscle-splitting incision. Pus which can be reached without trauma is removed by aspiration. A sump drain is inserted into the pelvis to drain it and the right lower quadrant. Powdered sulfonamides may be applied and the wound is closed about the drain in layers with fine steel sutures. The drain is anchored to the skin with No. 32 wire and modified Ochsen treatment is used.

The drains themselves vary greatly in size both as to length and diameter and in the size of the perforations in the outer tube. The larger-sized perforations are more satisfactory for thick exudate. The smaller perforations are suitable in cases with a thin watery exudate, particularly one composed of or containing bile. Perforations larger than 2 mm. may allow the entrance of omental tabs or even intestinal wall. In the photograph it can be noted that the drain protrudes a short distance above the skin level, even when dressings are applied. A thin dry gauze pad and a small aluminum cage is applied about this protruding portion which protects it from displacement by the bedclothes and from contamination, but does not interfere with the free passage of air down the outer tube as illustrated in the drawing.

Once the "sump set-up," consisting of drain, bottle, and motor is connected its care is quite simple. It is important to check the components of the unit for efficiency before it can be considered effectual. By clamping the tube to the motor and observing the rapid rise of the pressure gauge, one proves pump efficiency. By clamping the tube between the drain and the bottle the important fact that the bottle is air-tight can be determined by a steady rise of the vacuum gauge to the limit. Next the patency of the inner tube is checked by sudden release of this block. A characteristic sump suck and gurgle is heard as the built-up vacuum is opened to the abdominal portion of the drain. When there is abundant drainage the glass adaptor tube and bottle give visual evidence of function.

The most common difficulty encountered, namely blocking of the inner tube by exudate, frequently can be discovered by simply walking by the patient's bed. The block results in a progressive vacuum, and the motor can be heard laboring to maintain the level. Further examination will show the vacuum gauge to have risen above zero, and the blocking off of the tube from drain to bottle with sudden release does not result in the characteristic suck and gurgle. This difficulty can be readily solved by removing and cleaning the inner tube or by inserting a new one. When the perforations of the outer tube become blocked due to drying and crusting of the slight residual exudate, it is usually time for the drain to be removed. However if exudate is still present in the peritoneal cavity an applicator soaked with peroxide and swabbed about vigorously within the tube often results in dissolution of these obstructing crusts, and further drainage may occur.

Removal of the drain is a welcome contrast to the usually difficult and often traumatic removal of

gauge and rubber drains. In most cases cutting of the wire suture and a gentle, steady pull result in a painless removal with no bleeding. On occasion omentum may enter the perforations and cause some drag with pain. Rotation of the drain will release these attachments. The small aperture in the incision decreases considerably on removal of the drain, and the tract remaining lends itself readily to catheter drainage for progressive shortening to avoid pocketing. In several patients whose drainage was never profuse or odorous, this step has been omitted.

The steel sump drain lends itself most readily to cleansing and sterilization. Sterile sets of these drains are kept in the operating room at all times for selection when needed. They are most durable and last for indefinite periods with a minimum of care. Any standard noiseless continuous suction motor is efficient.

The principles of the sump drainage technique are most important:

1. The drain is made of stainless steel and causes no demonstrable irritation to tissue.
2. It should be placed into the most dependent part of the infected cavity. The patient's position should promote gravity drainage of exudate into this dependent area.

3. Only liquid exudate is subjected to the vacuum. No direct suction is made at any time against bowel, omentum or soft tissue unless dressings are erroneously allowed to seal the protruding end of the large tube. It is essential for proper functioning of the drain that there be free access of air and that there be sufficient space between the inner aspirating tube and the outer collecting tube to allow for its passage or else a vacuum against the bowel and omentum will occur.

4. Simple tests should be made frequently to insure proper function of the drain, bottle, and motor. If the vacuum gauge rises above zero there is blockage.

BENJAMIN GOLDMAN M.D.

ANESTHESIA

Cooper, W. G., II; Zumwalt, W., and Sugerbaker, E. D.: A Limited Comparison of Continuous Spinal and General Ether Anesthesia. *Surgery* 1944, 16: 886.

A comparison is made of 100 consecutive patients receiving general ether anesthesia and 100 consecutive patients receiving continuous spinal anesthesia. One anesthetist gave all of the ether anesthetics and another gave all of the spinal anesthetics. The patients were essentially similar in both series being indigent patients suffering from cancer with an average age of about sixty years and with many associated diseases other than the kind for which they were being operated upon. The relative consistency of all factors in both series with the exception of the type of anesthetic used made these series unusually good for comparative purposes.

It was noted that 44 per cent of the patients given ether anesthesia and 77 per cent of those given con-

tinuous spinal anesthesia were considered to have had satisfactory operative and postoperative courses. The incidence of hypotension was less in the spinal anesthesia cases and the occurrence of 3 fatal pulmonary emboli in the general-ether group alone seemed significant to the authors, who believed that the less complete relaxation produced by ether probably necessitated greater operative trauma. The technique of the continuous spinal anesthesia was described in detail. Routinely, a catheter was placed in the urinary bladder throughout the entire course of surgery. A stomach tube was inserted in patients in whom gastrointestinal surgery was planned and was permitted to drain throughout the surgical procedure. Oxygen was given intranasally when the anesthetic was given high in the spinal column and ephedrine was used intravenously at the beginning of the operation and intermittently when needed during the operation. Certain modifications of the Lemmon technique and apparatus are enumerated.

The continuous spinal anesthesia seemed superior because of three factors: (1) there is complete and sustained relaxation; (2) it does not necessitate hurrying on the part of the surgeon; (3) it is especially advantageous in patients with cancer because of the element of uncertainty in all exploratory procedures in which the operability must remain in question until the peritoneum is open. **MARY KARP M.D.**

Hingson, R. A.: Continuous Caudal Analgesia. *An Interim Report. J. Am. Med. Ass.*, 1944, 126: 1129.

The author reviews the status of continuous caudal analgesia on the basis of 42,000 parturients with comfortable labors and deliveries of babies born without narcotization and anesthesia. The average spontaneous breathing time of the baby from the moment the head was born was thirteen seconds, and the average lusty crying time was twenty-two seconds. The fetal mortality in this series was 1.7 per cent as compared with the fetal mortality of 5.2 per cent as registered for the entire United States. Sixteen maternal deaths occurred; 6 of these were attributed to obstetric complications, 7 to the misuse of caudal analgesia in unskilled hands and 3 were considered anesthetic deaths.

The author condemns the use of this method for the relief of discomforts of preliminary and early labor and advocates general anesthesia for the parturient in whom fear is uncontrolled.

The anatomy of the sacrum is reviewed. Malformations of the sacrum have been found to be more frequent than malformations of any other bone in the body.

The neurology of the cervix and uterus, from a study of 3,000 personally observed and managed obstetric cases, showed a natural anatomic dissociation between the motor and sensory components of the uterine nerves. Blocking of the eleventh and twelfth thoracic nerves was accompanied by total relief of abdominal cramps.

The three chlorides of Ringer's solution were considered the best diluent to intensify and prolong the

action of metycaine on the nerves in the peridural space

The hypotension which may occur is combated by the use of 50 mgm of ephedrine sulfate as needed, by the elevation of the extremities to be at right angles with the body and by the use of 100 per cent oxygen inhalations. The occurrence of this hypotension is utilized in the pre-eclamptic patient, in the eclamptic patient with convulsions, and in the medical case with essential hypertension. In all of these types of cases striking clinical improvement occurred immediately after the institution of the caudal analgesia. This improvement was probably due to the peripheral vasomotor dilatation of the pelvis and lower extremities and the vasomotor changes in the kidneys, with an associated increase in the output of urine. The method is suggested for the treatment of thrombophlebitis, sciatica, intractable pain of pelvic carcinoma, ureteral and vesical colic, Dietsch's burns of the lower extremity arterial emboli of the legs, and peripheral vascular angiospastic diseases. It is also indicated in operations below the umbilicus in the debilitated, aged, cachectic patient, and in the management of industrial and war trauma of the lower half of the body.

One hundred and sixty cesarean sections have been performed under this method without loss of mother or baby.

The malleable stainless steel caudal needle has almost eliminated the hazard of needle breakage. The urethral catheter has advantages for parturients who are unco-operative, and for those eclamptic patients who have lost motor control of their central nervous system. The continuous drip technique with modifications by Siever is mentioned. The latest modification is the author's introduction of the nontraumatic nylon needle which is inserted by means of a stiff steel stylet that is withdrawn as soon as the sacrococcygeal ligament is penetrated.

Emphasis is made on the newness of the continuous caudal analgesia technique, with a request for caution in its use.

MARY KARP M.D.

Hellman, L. M., Shettles, L. B., Manahan, C. P., and Eastman, N. J. Sodium Pentothal Anesthesia in Obstetrics. *Am. J. Obst.*, 1944, 48: 85

Between September 1, 1940 and March 31, 1944, 1,415 deliveries were carried out at the Johns Hopkins Hospital, Baltimore, under sodium-pentothal anesthesia.

The amount of sodium pentothal necessary for low forceps delivery together with episiotomy and repair lies between 0.75 and 1.0 gm. (from 15 to 20 cc. of a 5 per cent solution) provided that some form of sedation has been administered in labor such as a barbiturate or paraldehyde. For cesarean section 1.5 gm. (30 cc. of a 5 per cent solution) is the quantity usually required. The amount is never allowed to exceed 3 gm. Except in cases in which scopolamine has been given atropine (0.5 mgm. or 1/130 gr.) is routine. Due to mechanical difficulties this anesthesia is not suitable for spontaneous deliveries.

TABLE I.—ANALYSIS OF 963 OPERATIVE DELIVERIES UNDER SODIUM PENTOTHAL ANESTHESIA ACCORDING TO TYPE OF OPERATION

Low forceps	777	(80.7%)
Cesarean section	14	(1.5%)
Breech extraction	51	(5.3%)
Vernix and extraction	5	
Craniotomy	3	
Mildforceps	3	

Although the relaxation of the abdominal walls provided by sodium pentothal is not sufficient for many abdominal operations, it is quite adequate for cesarean section. Bleeding is less than with gas-oxygen-ether as is also in the authors' opinion, postoperative distention. Except for versions on second twins, sodium pentothal is ordinarily contraindicated for this operation because the uterus does not relax well.

There is a period of five minutes after starting the anesthesia during which the amount of drug reaching the fetus is very small and throughout the first ten minutes this amount is decidedly less, as a rule, than after fifteen or twenty minutes of the anesthesia.

TABLE II.—MG/100 BLOOD ACID PENTOTHAL IN MOTHER AND CHILD AT DELIVERY

Gm. of Sodium Pentothal given	Duration of Anesthesia in minutes	Mother MG/100	Infant MG/100
7	5	3.0	8
0.45	6	3.5	1.4
0.35	7	3.4	1.25
0.55	9	3.0	1.75
0.40		2.5	3.0
0.00	2	6.2	5.0
55	15	0.75	5

As far as the authors have been able to determine, there was no instance in the entire series of 1,415 cases delivered under sodium pentothal anesthesia in which the anesthetic agent was directly responsible for an infant's death or in which it played any demonstrable role.

It is the authors' impression that blood loss is less with sodium pentothal than with gas-oxygen-ether. The incidence of postpartum hemorrhage in the present series (600 cc. or more) was given as 2.8 per cent.

There were 2 maternal deaths in the series. Both patients were colored; they were nineteen and sixteen years of age, respectively; both were primiparas and both presented symptoms of severe toxemia of pregnancy.

Sodium pentothal has been employed successfully in approximately 500 additional obstetric operations not intended for immediate delivery of the infant—notably in puerperal tubal ligation, completion of incomplete abortion, artificial rupture of the membranes for the induction of labor and manual removal of the placenta.

EDWARD L. CORNELL, M.D.

Hayman, I. R.: *Experiences with Anesthesia in Combat Areas. War Med. Chic.* 1944 6 353

The duties of the anesthetist in the combat area includes not only the administration of the anesthetic agents but preoperative and postoperative care of casualties.

Shock therapy of the casualty patient is discussed with the related derangement of the cardiovascular and respiratory system. Respiratory emergencies are enumerated including the relaxed tongue foreign bodies, laryngospasm tension pneumothorax and open wounds of the chest. The immediate treatment of any condition that impaired tidal exchange included the administration of morphine tartrate in 1/4-gr doses however morphine was not given when head injury was possible or when increased intracranial pressure was evident. The use of oxygen or air under pressure, the intravenous injection of atropine, and intubation were the procedures of choice when laryngospasm occurred.

Tension pneumothorax is the result of a laceration of the the lungs and bronchi with the formation of a bronchopleural fistula. Treatment involves the reduction of the elevated intrapleural pressure and is most easily accomplished by the insertion of a short needle of wide bore.

It is important to recognize and treat the incipient insidious anoxia. A patient with slight anoxia may present a picture with symptoms of alcoholic intoxication, euphoria, ataxia, muscular weakness, impairment of muscular function, amnesia, and diminution of the special senses. The administration of oxygen by catheter or Boothby mask technique was used for this condition with gratifying results although the supply of oxygen which was available with the British in Tunisia was limited.

The available anesthetic drugs are outlined and the choice of an anesthetic agent is discussed. Pentothal sodium (given intravenously) was used far more than all other agents. It was usually necessary for the anesthetist to be responsible for several anesthetics going at the same time. For all abdominal operations anesthesia was induced with chloroform, ethyl chloride, or pentothal sodium followed by open or endotracheal ether-oxygen anesthesia. Most of the men with head injuries received treatment under local anesthesia. Spinal anesthesia was resorted to in only a few instances, as it was not considered suitable for battle casualties in the front lines within a few hours after injury one could not be certain of cardiovascular stability in spite of the apparent absence of shock. Block of the lumbar

sympathetic ganglions was performed in only a few cases in an attempt to increase the peripheral circulation of the lower extremities and blocks of the brachial plexus and of the median ulnar and radial nerves at the wrist were occasionally done for the surgical treatment of the arm and hand.

MARY KARP M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Shelden, C. H. and Pudenz, R. H. Improved Retractor for Hemilaminectomy *Surgery* 1944, 16 884.

In order to obtain adequate exposure for successful removal of protruded intervertebral discs Shelden and Pudenz constructed a retractor which facilitates hemilaminectomy. It consists of two blades of unequal lengths, the shorter having three long teeth which are inserted through the lumbar fascia adjacent to the spinous process. The longer blade is 2 inches wide slightly curved and has small laterally bent serrations on the free end these permit fixation at any desired depth in the muscle. The two blades are attached to the arms of a Liffenthal rib spreader which allows exchange of blades.

Fig. 1. Exposure for hemilaminectomy demonstrating method of muscle retraction.

The practical use of the retractor is shown in the accompanying illustration. Hemilaminectomy is simplified and exposure improved, particularly in patients having strong muscles. The instrument is adapted for use in the cervical region.

STEPHEN A. ZEEMAN M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Gomez, G. E.: The Present Value of Roentgenology in the Diagnosis of Appendicitis. *Am. J. Roentg.* 1944, 5: 624.

In this discussion on pathology of the appendix as determined roentgenologically the author bases his remarks on chronic and recurrent appendicitis and observations made on 21,000 gastrointestinal examinations and conclusions reached by other writers.

The author's conclusions relative to appendiceal disease are reached after careful examination of the gastrointestinal tract and gall bladder to eliminate these as the source of symptoms by careful and repeated examinations.

Having excluded the possibility of disease elsewhere he then searches for direct x-ray evidence of changes in the appendix, such as abnormalities in its size, shape, and position, and evidence of its physiological change such as its ability to fill and empty. The latter apparently has a direct bearing on its pathological state since an appendix which does not fill or delays in emptying itself is indicative of a disease process.

Indirect x-ray evidence of pathology is based on the reflex signs that can be elicited. These include pain over the appendix, pylorospasm which produces a six hour gastric retention and tenderness on palpation of the pyloric area, aerogastria in six hours, increase in size and density of the liver shadow and evidence of ileal spasm and ileocecal spasm.

On correlation of these findings with the clinical symptoms, the diagnosis of an active process can be determined.

R. A. BRASER, M.D.

Oppenheimer, A.: Roentgen Diagnosis of Incipient Cancer of the Rectum. *Am. J. Roentg.* 1944, 53: 637.

The author describes a technique for x-ray study of the rectum and sigmoid. In this procedure very small amounts of barium are employed and spot films or oblique films of the region in question can be made for the study of early lesions. While the method requires a little extra work the time consumed is not great and the results reward the extra effort.

A small rubber catheter is inserted into the rectum and with an attached syringe, controlled amounts of barium are gradually injected into the rectum to a desired filling. After roentgenoscopy and filming the catheter can be connected to the regular enema apparatus for further filling and study of the colon.

By this method the author has been able to discern small lesions of the rectum, particularly small malignant ulcers which would otherwise have been overlooked. Likewise, other intraluminal and extraluminal lesions, which would be obscured by the regular massive filling of the rectum, can be found and differentiated.

R. A. BRASER, M.D.

Vaughan, W. W., and Elchwald, M.: Priodax: A Contrast Medium for Cholecystography. Analysis of 163 Cases Outlining the Various Reactions in 3 Techniques and the Operative Findings in 22 Cases. *Radiology* 1944, 43: 578.

Cholecystography is a routine procedure in the study of gall-bladder disease. The high accuracy of this procedure (95 per cent) emphasizes the clinical importance of this study.

Since the original work of Graham and Cole on gall-bladder visualization by intravenous injection of tetrabromophenolphthalein, science has been striving constantly to improve the method by use of various chemicals and techniques. Tetraiodophenolphthalein was substituted for tetrabromophenolphthalein less than one year after the original (Graham Cole) publication and remained the chemical of choice until the recent advent of priodax.

The clinical use of priodax (bilmolecetan, as it was called in Germany) was first described by Kleiber in 1940. This dye was used on 55 patients and the results were verified by surgical exploration. In addition to the fact that it was an excellent contrast medium, it minimized the extent of diarrhea, nausea, and vomiting.

Priodax is a white, odorless powder soluble in alkali, ether, alcohol, and acetone, but almost insoluble in water. Experimental studies showed that the lethal dose with oral administration was 1,000 mgm. per kilogram of body weight. Fifty per cent of the priodax used is excreted through the urinary tract, in contrast to the 10 per cent of tetraiodophenolphthalein when the latter is used. The remainder of the tetraiodophenolphthalein is excreted through the gastrointestinal tract, which is undesirable from a roentgenographic viewpoint. Priodax is available in tablets of 0.5 gm. each, the dosage is 1 tablet per 25 pounds of body weight. Tablets should be swallowed with or without fluid, but should not be chewed.

The authors report a series of 163 cases in which priodax was used. The single-dose method was used in 51 cases; a divided dose was given in 55; and a double dose in 57 cases. The usual preliminary preparations were followed. In the single-dose method, 6 tablets were given following the fat-free evening meal; in the divided dose, 3 tablets were given following the noon meal and 3 following the evening meal; in the double dose, 6 tablets were given after the noon and evening meals.

Toxic effects with the use of priodax, given by the various methods, were infrequent and minimal in comparison with those following the use of tetraiodophenolphthalein. Roentgenologically the gall-bladder shadow was a little more dense with the use of the double-dose method; however it was satisfactory in all methods. For purposes of economy and standardization, the single-dose method is used.

In 22 of 226 examinations surgery confirmed the roentgen findings of a pathological gall bladder. In 1 instance of nonvisualization of the gall bladder a normal gall bladder was found at surgery. This patient, however, had clinical jaundice with an icteric index of 44.

MAURICE D. SACNA, M.D.

Heublein G. W.: The Roentgen Diagnosis of Traumatic Lesions of the Cervical Spine. *J Am Med Ass* 1944, 126: 950.

The author reports on the newer developments of apparatus and technique at the Percy Jones General Hospital Battle Creek, Michigan which permit an accurate roentgen diagnosis of traumatic lesions of the cervical spine and includes several valuable illustrations to prove his statements.

The acquisition of the Morgan meter which is not as yet in general use has helped considerably in the making of good roentgenograms of both simple and difficult projections of the cervical spine. The operation of the meter depends on the fact that intensity X exposure time = a constant. Thus if the intensity reaching the film is known in advance the time for proper exposure can be read off directly from a calibrated scale on the meter. By this method excellent roentgenograms can be obtained even through heavy plaster casts.

In addition to routine anteroposterior and lateral films at a distance of 6 feet, roentgenograms are being made through the open mouth in oblique (from 50 to 55 degree) projection and in the Jackson position, similar to an exaggerated Waters position which is used in the examination of the paranasal sinuses.

In this institution fractures of the cervical spine comprise 23 per cent of all spinal fractures. They are of two types: (1) those which affect the cord protecting portion of the spine, i.e. the neural arch and its processes and (2) those which affect the weight bearing structures of the spine i.e. the vertebral bodies. The latter vary from minute spicules projecting anteriorly or as a moderate bulge along the

anteroposterior border of the body to considerable compression of the spongy portion. Dislocations are observed with or without fracture, in sharp contrast to the dorsolumbar spine where dislocations almost invariably are associated with fractures. Soft tissue swellings adjacent to the vertebral bodies are also found to be of significance as they indicate hemorrhage, edema, or infection. In fractures of the arches callus formation often constitutes the most prominent feature.

Certain special procedures are also stressed by the author. Thus in not a few of the cases it is advisable to make roentgenograms in the lateral view with the neck in flexion and extension. Exposures made in flexion may show a subluxation not demonstrable in conventional views. In other instances delayed roentgenograms serve a better purpose. This applies especially to the fractures running through the base of the odontoid process which may be completely missing at the initial examination but may be revealed some weeks later after a rarefying osteitis has developed along the fracture line. Injuries to the intervertebral discs are often advantageously demonstrated by pantopaque myelograms. Successful delineation of such lesions however is not always an easy task.

Accurate diagnosis depends on several important factors such as (1) proper apparatus including canvas support and a special attachment for obtaining lateral films in the prone decubitus (2) adequate extension of the neck to prevent escape of the opaque material into the basal cisterns (3) experienced spinal puncture a factor which cannot be too strongly emphasized (4) proper withdrawal of the opaque medium at the end of the examination to be checked by a scout film of the area examined and (5) the closest correlation of the clinical and roentgenographic findings.

The general conclusion is reached that the roentgen examination is an invaluable aid in the diagnosis and differential diagnosis of traumatic lesions of the cervical spine.

T LYUCOMA, M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Najjar, V. A., Holt, L. E. Jr., and Royston, H. M.: A Note on the Minimum Requirements of Man for Vitamin C and Certain Other Vitamins. *Bull. Johns Hopkins Hosp.* 1944, 75: 315.

A group of 7 young adults were given for a period of eighteen months a diet in which all water-soluble vitamins were provided as pure principles in carefully measured quantities. With the exception of thiamine, the intake of which was gradually reduced until deficiency symptoms appeared the vitamins were in quantities which did not vary throughout the entire experimental period. No symptoms of any deficiency other than that of thiamine were observed. These experiments do not define the minimal requirements of these factors, with the exception of thiamine, which is discussed elsewhere. They do however establish upper limits for the minimal requirement. Of particular interest are the observations on ascorbic acid, which confirm those of Pilgou and Losner that scurvy does not develop on a daily intake of from 8 to 25 mgm. of ascorbic acid.

Ruffin, J. M., Cayer, D. and Perlweig, W. A.: The Relationship between the Clinical Picture of a Mild or Early Vitamin Deficiency and Laboratory Determinations of Vitamin Levels. *Gastroenterology* 1944, 3: 340.

The frequency of full-blown vitamin deficiencies such as beri-beri, pellagra, and scurvy is decreasing rapidly and they no longer constitute a serious problem in North Carolina. It is reasonable to assume that for every advanced vitamin deficiency there must be many mild or early avitaminoses. It is difficult to determine whether one is dealing with a patient having a true vitamin deficiency or only a constitutionally inferior individual. Correct diagnosis is of greatest importance then for the intelligent use of vitamin therapy.

Recently laboratory procedures for measuring vitamin levels in the blood and urine have been devised and standardized. The application of these procedures in diagnosis may be extremely valuable if the patients with unquestionable evidence of vitamin deficiency prove to have significantly lower levels than normal controls. The authors undertook this study in an effort to determine if there was a relationship between early clinical vitamin deficiency and the laboratory determination of vitamin levels.

Two groups of patients were selected. The first, with vitamin deficiencies, were patients with glossitis, papillary atrophy of the tongue, cheilosis, or peripheral neuritis who showed the most reliable evidence of B-complex deficiency. All 26 patients selected gave a history of an inadequate diet and one or more of these findings. All were ambulatory free of or-

ganic disease, and without a history of recent vitamin therapy.

The second group were the controls who were again divided into a groups (a) patients with no definite evidence of a deficiency state and who ate the usual diet of an average tenant farmer. They presented a variety of neuroathenic complaints and represented constitutionally inadequate individuals with organic disease and (b) normal students, technicians, and dietitians, all of whom had been subsisting on an apparently adequate diet.

In evaluating the vitamin tests the figures comprising the lowest 10 per cent of the normal control group were arbitrarily selected as being the suggested lower limit of normal values since there was little agreement in the literature as to what constitutes the lower limit of normal.

The laboratory examinations for determining vitamin levels were carried out on blood plasma for vitamins A, C and carotene. B-complex vitamins were determined in the urine before and after a test dose, by chemical or biological assay.

The distribution of vitamin A and carotene levels showed a statistically significant difference between the normal controls and the deficiency group with the ward controls falling midway between the two. Although no clinical evidence of an A deficiency was observed in any patient, this study indicated that low levels of plasma vitamin A and carotene are likely to occur in patients in this locality with a mild deficiency of B complex.

The vitamin C values showed a wide discrepancy between the suggested lower limit of normal (0.15 mgm.) and the generally accepted value of 0.6 mgm. Nearly 50 per cent of the normal controls had values of vitamin C which fell below 0.6 mgm., and the authors believe this value is possibly too high. The higher vitamin C values are more apt to occur in normal individuals, but the distribution was so wide that there was no statistical significance between the two groups.

There were striking statistical differences between the two groups observed in the urinary excretion levels of nicotinic acid, riboflavin and thiamin, the greatest variations being found in nicotinic acid levels. There was little difference in the pyridoxine values of the two groups, which suggested that pyridoxine deficiency is not likely to occur in B-complex deficiencies, a point in keeping with the authors' clinical impression.

Most patients in the deficiency group had levels below the suggested lower limit of normal in more than one vitamin (22 of 26 when the B complex alone was considered, and 21 of 26 if vitamins A and C and carotene are included). Twenty-four of 26 patients classified clinically as having a B-complex deficiency had levels below the suggested lower limit of normal in nicotinic acid, riboflavin, or thiamin.

It appears then that patients having clinical evidence of a deficiency state based on the criteria enumerated are very likely to have levels which fall below the suggested lower limit of normal in one or more members of the B complex. If observations made in this study are confirmed by subsequent study laboratory determinations may become useful procedures in the recognition of early deficiency states.

ROBERT BUCKLOW M.D.

Volpitta P. P., Woodbury R. A., and Abreu B. E.: The Influence of Different Forms of Mechanical Artificial Respiration on the Pulmonary and Systemic Blood Pressure. *J Am Med Ass* 1944 126 1066.

An improved technique has been developed for the measuring of the effective pulmonary and the effective systemic blood pressure in animals with a closed chest. The pulmonary and systemic blood pressures have been recorded while respiration was maintained with the individual use of seven resuscitators.

One sound was inserted into the exposed left carotid artery on into the aorta, past the semilunar valves, and into the left ventricle. The other sound was inserted into the exposed external jugular vein down to the superior vena cava and right auricle into the right ventricle.

Cardiac arrest was produced (1) by complete occlusion of the airways in 3 dogs (2) by use of the bellum with carbon-dioxide-absorption technique in 3 dogs and (3) by electrically induced ventricular fibrillation in 3 dogs.

No matter what method of mechanical artificial respiration was used, recovery of the animal was accomplished when respiratory arrest and slow, weak cardiac contractions were produced by the administration of helium with the carbon-dioxide-absorption technique. No significant change was produced in the pulmonary and systemic blood pressures with any of the methods of resuscitation studied.

Any blood flow produced by the resuscitators did not reach the coronary and cerebral arteries. On the other hand blood was pushed toward the extremities and cutaneous areas.

Intrapulmonic positive pressure greater than 10 or 12 mm. of mercury if maintained for a prolonged period of time may hinder venous return to the right side of the heart.

RICHARD J. BENNETT JR. M.D.

Henry, F. M., Lawrence, J. H., Bridge, E. V. and Williams, O. L.: Protective Effects of Preoxygenation on Abdominal Gas Pain; Results of a Study of Preflight Breathing of Oxygen on Pain Resulting From Decompression to 23,000 Feet. *War Med., Chic.*, 1944, 6 395

The denitrogenation resulting from the breathing of oxygen has been reported to relieve postoperative and obstructive abdominal gas distention in human beings and has been found to reduce the total amount of gas in an isolated intestinal loop in dogs.

Radioactively labeled inert gas introduced into the stomach and lower part of the bowel of human subjects is excreted by the lungs in proportion to the pressure gradient. Swallowed oxygen would be expected to cause less trouble than swallowed air because of its additional metabolic elimination. In view of these observations it occurred to the authors that the incidence and severity of pain due to the expansion of gas in the digestive tract resulting from decompression in an altitude chamber or in an aircraft might be reduced by the preflight breathing of oxygen.

A control series of 80 healthy young males was decompressed twice to 38,000 feet and exercised at that altitude for ninety minutes. Breathing of pure oxygen began nine minutes before the altitude was reached. A similar group made three ascents under the same conditions except that the breathing of oxygen began one third hour one hour and two hours before the altitude was reached. 61 of these subjects made all three ascents.

In 20 per cent of the controls definite gas pain developed with prebreathing of oxygen for one third hour the incidence dropped to 23 per cent with one hour it was 10 per cent and with two hours only 10 per cent. Moderately severe gas pain occurred in 8.4 per cent of the subjects in the control runs, in 5.8 per cent in the one third hour runs and in 2.7 per cent in the one hour preoxygenation runs. No pain of this or greater severity occurred with two hours of preoxygenation.

Detailed examination of the data yields no evidence that differences in decompression experience diet or elapsed time between meals and ascent can account for the observed protection.

Definite gas pain appears to have a higher incidence if decompression occurs three hours after eating than is the case if the elapsed time is only one or two hours.

It is concluded that two hours of preoxygenation causes a decided reduction in the incidence and severity of abdominal gas pain resulting from decompression to 38,000 feet (11,400 meters).

JOHN E. KIRKPATRICK, M.D.

Kritzer, R. A.: Acute High Altitude Anoxia; Gross and Histological Observations in 27 Cases. *War Med., Chic.*, 1944, 6 369.

Fatalities in air crews, due to deprivation of oxygen during bombing operations at high altitude, have afforded an opportunity to study the gross and microscopic anatomy of acute anoxia in man as it occurs at a low atmospheric pressure.

In 1942 Mueller and Rotter described 4 cases of acute high-altitude anoxia among air crews of the Luftwaffe. They found congestion of all organs of the greater circulation which they attributed to right ventricular failure and to peripheral vascular collapse. In all cases these authors noted an absence of clotting of the blood. Fat free vacuoles, either optically empty or partially filled with refractive granules staining lightly with eosin, were present in

the livers of all patients. In heart muscle cells the vacuoles were observed to be adjacent to and deforming the nuclei, and they were frequently arranged in continuous strands appearing as a "string of pearls." The vacuoles were considered similar to those described by Pichotke, Hesse-Ladewig, and Trowell.

Twenty-seven autopsies were performed during 1943 in one hospital on members of high-altitude bomber crews in whom death had been attributed to anoxia by the Air Force medical officers who investigated the cases. In no instance was the analysis of the history complicated by the presence of wounds. In no case was a rapid ascent to high altitude recorded. Although the possibility of fatal air embolism was not considered likely at the altitude at which death occurred a search for intravascular gas in the right ventricle and in the mesenteric veins was made in 16 successive cases. None was found. In general the casualties occurred at altitudes of from 24,000 to 31,500 feet (7,300 to 9,630 meters), but in many instances the precise level at which difficulty was encountered could not be determined because the exact time of death was not always known by crew mates.

A study was made of the findings at autopsy in 27 cases of acute high-altitude anoxia. Widespread, severe capillary congestion was found. This was conspicuous and most constant in the pulmonary renal, intestinal, and cerebral capillaries. The skeletal muscle did not have this congestion. In a high proportion of cases the systemic venous and the portal circulations showed gross and microscopic congestion, and the right ventricle was dilated. There was wide individual variation in the incidence, location, and amount of edema and hemorrhage. An exception to this was the consistent occurrence of hemorrhage in the thymus and in the middle ear. Swelling of the endothelial cells of capillaries of the renal medulla was observed. The presence of fat-free and glucogen free vacuoles, previously described, in the myocardium and liver and less frequently in cells of other organs, was confirmed. These vacuoles occurred with equal frequency in cases of anemic anoxia (acute carbon monoxide poisoning) but were rarely found in the tissues in nonanoxic control cases.

JOHN E. KIRKPATRICK, M.D.

Brues, A. M., and Shear, M. J.: Chemical Treatment of Tumors. Reactions of 4 Patients with Advanced Malignant Tumors to Injection of a Polysaccharide from *Serratia Marcescens* Culture Filtrate. *J. Nat. Cancer Inst.* 1944, 5, 95.

Certain preparations of bacterial origin when administered parenterally to animals bearing sarcomas produce hemorrhage in the tumors within a few hours. The action is highly selective, for while severe hemorrhage is induced in the tumor it has not been reported to occur in any of the normal tissues with a few minor exceptions of slight degree. The hemorrhage and necrosis produced in this way are followed in some instances, by complete and permanent regression of the tumor.

The bibliography on the treatment of human tumors with induced bacterial infections or with bacterial products began about seventy five years ago. Interest in the effect of bacterial preparations on tumors in experimental animals was revived in 1931 by the report of Gratia and Linx. Because of the high toxicity of such bacterial preparations, Shear and Andervont separated the active agent from toxic and inactive constituents. They obtained a polysaccharide fraction from filtrates of cultures of *Serratia marcescens* (bacillus prodigiosus) one of the organisms used in the preparation of "Coley's mixed toxins."

This product was used by the authors in 4 patients with advanced malignant tumors (prostatic carcinoma, lymphosarcoma, multiple myeloma, and Ewing's sarcoma) in the form of muscular injections. All of the patients died with tumors. Two patients showed noteworthy relief of their symptoms. To showed evidence of hemorrhage in the tumors at postmortem examination, although it was not possible to decide whether this finding was related to the treatment. The patient with multiple myeloma showed no evidence of any effect of this agent on the tumor.

Following initial chill and fever, a prolonged period of hypotension, sometimes with anuria and cardiac decompensation occurred. Some of these reactions may have been the consequence of rapid absorption of products of destruction of the tumor tissue.

The 2 patients showing symptomatic relief also showed chemical evidence of the rapid breakdown of nitrogenous substances. This fact suggested that tissue protein including nucleoprotein might have been destroyed.

The findings in this preliminary study do not warrant the conclusion that this polysaccharide should be recommended in the treatment of patients with malignant tumors. The reactions in 2 cases, taken in conjunction with the results of animal experimentation, suggest that further investigations may yield interesting results. However great caution must be exercised even in the experimental employment of this material in patients. Small doses may provoke violent reactions, and death may follow in a short time unless precautions are taken to counteract the undesired responses.

JOSEPH K. NARAT, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Hodges, R. G.: The Use of Sulfadiazine as a Prophylactic against Respiratory Disease. *J. Experimental Med.* 1944, 31, 817.

In this experimental problem in which sulfadiazine was used as a prophylactic measure against respiratory diseases, the author had somewhat of an ideal condition for experimentation. The two groups of individuals used for controls and studies had been observed over a period of time before the experiment, and lived under similar environmental circumstances.

Since these groups were under close supervision the date obtained is worth consideration.

The effect on total respiratory disease after the administration of 2 gm of sulfadiazine per day reduced the incidence to one-third and one-half of the control group. Throughout the experiment a variety of dosages were tried. No definite amount is recommended but an optimal amount for a given group should be worked out individually. No serious untoward reaction occurred in this study.

The most striking effect was obtained in streptococcal sore throat and scarlet fever in which the incidence dropped to zero.

In pneumococcal infections there was a significant drop, but since there was also a decline in upper respiratory infections the drop was hard to evaluate. Atypical pneumonia, likewise, displayed a low incidence but the number of cases were too few for significant analysis.

Acute rheumatic fever was less prevalent during this study and fell below the expected rate.

R. A. BRIDGER, M.D.

DUCTLESS GLANDS

Broders, A. C., and Parkhill, E. M.: Diffuse and Adenomatous Goiter and Goiter Induced by Various Agents. *Surgery* 1944 16 633

The diffuse colloid goiter which used to be observed frequently from prepuberty to late adolescence according to Haines is rarely observed today by the clinician. Furthermore it is almost never seen by the surgical pathologist.

Since the advent of administration of a compound solution of iodine the typical meaty exophthalmic goiter is seen much less frequently and has for the most part been replaced by a gland comparable to a colloid goiter although smaller. The change in the exophthalmic goiter also is undoubtedly attributable to administration of the compound solution of iodine. Following the administration of a compound solution of iodine, the epithelium changes from columnar to a low cuboid or flat type and the acini dilate or at least have larger lumina, and their colloid content is increased. This increase in the size of the lumina is probably the result of the diminution in the size of the cells. Some exophthalmic goiters on the other hand, are more or less resistant to the changes that usually take place after the administration of a compound solution of iodine.

The nodules sometimes observed in hypertrophic parenchymatous thyroid or exophthalmic goiters with or without adenomas differ from the true adenomas of exophthalmic goiter in that they are not encapsulated rarely contain true fetal acini, and under the microscope usually resemble the extranodular part of the goiter. In other words the nodules are to a large extent comparable to the nodules observed in hyperplasia of the prostate gland.

In all hypertrophic parenchymatous thyroids or exophthalmic goiters that is in the diffuse non-nodular the nodular and the adenomatous types,

varying degrees of chronic thyroiditis may be present. The chronic thyroiditis in these goiters is characterized by fibrosis and lymphocytic infiltration of the interfollicular tissue with or without the formation of germ centers. This inflammatory reaction is probably attributable not to bacterial activity but to toxic products of the goiter. To some extent this form of thyroiditis may be activated by a compound solution of iodine as it has been more in evidence since the therapeutic use of such a solution of iodine began.

Adenomas may occur singly but usually they are multiple. They vary markedly in size in consistency and from a light amber to a reddish brown in color and they are encapsulated. They may undergo various types of degeneration, such as hemorrhagic, fibrous, hyaline calcareous lipoid (granular) and cystic. Macroscopically and microscopically true adenomas differ from the surrounding thyroid tissue.

In recent years certain interesting and important forms of goiter have been observed after the administration of a variety of agents. Some of these goiters are now coming to the attention of the pathologist.

One of the first of these forms of goiter to be noted in man was that seen in patients receiving thiocyanates over a prolonged period in the treatment of hypertension.

Goiter produced by thiocyanates in many respects resembles a form of experimental goiter of great interest since it was first reported by Chesney, Clawson and Webster in 1928, the so-called 'cabbage goiter' or 'cyanide goiter'.

The cabbage goiters and the cyanide goiters like those produced by thiocyanate can be prevented by the simultaneous administration of iodine. The administration of iodine after the development of goiter in rabbits however resulted in the onset of symptoms of severe sometimes fatal, hyperthyroidism.

Other important compounds recently found to have powerful goiter-producing effects fall mainly in two groups (1) thiourea and various thiourea derivatives, and (2) sulfonamides and related substances.

Kennedy in 1942 reasoning that the goiter producing effect of rapeseed might be due to a derivative of urea, injected allylthiourea into rats and found that it produced large goiters. Richter and Clisby in 1942 produced marked hyperplasia of the thyroid of rats by the administration of phenyl thiocarbamide. MacKenzie, MacKenzie and McCollum in 1941 found that the administration of sulfaguandine to rats resulted in enlargement of the thyroid and in 1942 MacKenzie and MacKenzie produced goiters by administering thiourea, diethylthiourea, and allylthiourea as well as sulfaguandine and other sulfonamide compounds. Astwood, Sullivan, Bissell, and Tykowitz in 1943 produced enlarged thyroid glands in rats with both sulfonamide compounds and thiourea.

It is of interest that the experimental production of goiter by cyanides and thiocyanates has been prevented by the simultaneous administration of iodine whereas the goitrogenic effect of thiourea, sulfanilamide and related compounds cannot be prevented

by the administration of iodine but can be prevented by the administration of desiccated thyroid or thyroxin. The administration of desiccated thyroid or thyroxin was also effective in reducing goiters after they had developed regardless of whether they had followed the administration of cyanides, thiocyanates, thiourea, or sulfonamide compounds.

It has been assumed that the action of the various drugs which produce goiter is by means of an inhibition of, or interference with the manufacture of the normal thyroid hormone. The resulting increase in activity of the thyroid-stimulating pituitary hormone brings about hyperplasia of the thyroid cells but does not bring about an increase in thyroid hormone which is in fact reduced to subnormal levels. This inhibitory effect has been made use of clinically by the administration of thiourea or thiouracil to patients suffering from hyperthyroidism in the form of Graves disease. In addition to the disappearance of toxic symptoms and a decrease in the basal metabolic rate temporary increase in the size of the thyroid gland was observed in 3 of 9 patients treated with thiouracil by Williams and Bassell. Microscopically the thyroid gland in cases of Graves disease treated with thiouracil shows extreme hyperplasia with heightened epithelium, marked papillary infolding, and mitosis in the epithelial cells.

The authors said that in the thiocyanate goiter there is more cellular hypertrophy and it is therefore, more nearly comparable microscopically to an exophthalmic goiter and that the thiouracil goiter is

more of a cellular hyperplasia with mitosis very much in evidence and is therefore more comparable to a carcinoma of the thyroid.

Mahorney II: Goiter in the Southern States. *Surgery* 1944, 6 764.

Goiter is more common in the southern states, than it had been generally believed. It is more common in southern Louisiana than in the northern part and more common along certain bayous.

The surgical mortality is higher in the South and the surgical mortality of goiter is definitely higher in the negro than in the white man. The author thinks that this is due not so much to the greater severity of the disease in the negro but to the poorer physical surroundings before and after operation and hence the less prompt preoperative and postoperative response.

The author's material consisted of 101 patients who underwent 110 operations of these 7 were multiple-stage operations. Sixty-one patients were white and 40 were negroes. Fifty-five patients presented toxic goiters. There were 2 postoperative deaths, both of which might have been prevented by multiple-stage operations.

The author thinks that the negro should be added as a third group to the groups of the elderly and of the young who do not tolerate surgery well. Added cautiousness is necessary to determine the proper time and extent of the operation in the negro.

GAS GANGRENE

Collective Review

MAURICE D. SACHS, M.D., Grass Valley, California

GAS gangrene is a companion of wars and is worthy of serious reconsideration now that we are once again engaged in a world wide conflict. MacLennan (26) reports that in Africa and the Middle East, from September 1939 to October 1942 1 in 300 of the wounded had gas gangrene and half of those so infected died. Monroe (33) states that in the Southwest Pacific 1 in 150 developed gas gangrene, and if débridement was done within from four to six hours, there was a 40 per cent mortality but after another battle when no débridement was done and sulfonamide was given within from four to six hours (inadequate dosage) the incidence of gas gangrene was six times as high. In World War I reports are similar. In civilian accident cases, the incidence is lower and the mortality similar (30-46). Cramp (10) gives the incidence at Bellevue Hospital New York in 1912 as 1 in 600.

Unfortunately the literature discloses marked disagreement regarding the best method of treatment. Surely a disease of such high incidence and high mortality should be re-evaluated diagnostically and therapeutically.

DIAGNOSIS

Although more attention has been given to the diagnosis of gas gangrene in the present war the incidence has not changed appreciably during the last twenty five years, as evidenced by the incidence of 0.36 per cent in 1917 and 1918 and the present incidence of 0.32 per cent (28). The American Expeditionary Forces reported an incidence of 1.7 per cent in 1917 and 1918.

Gas gangrene was recognized as a clinical entity during the days of Hippocrates. However it was not until 1607 that one of the first clinical

descriptions was reported by Fabricius Hildanus (37). Subsequently the attention of the medical profession was directed to this disease during the Crimean War and American Civil War. As wars continued greater stress was placed upon the importance of early diagnosis and treatment of gas gangrene. Intensive studies were made during World War I and are being continued during the present conflict.

Gas gangrene presents a composite clinical picture (19) and should be differentiated from "an aerobic cellulitis" and "gas abscess," inasmuch as the presence of gas-producing organisms in a wound is not sufficient evidence to warrant the diagnosis of gas gangrene.

Anaerobic cellulitis may start as a simple contaminated puncture wound with no muscle involvement. The onset is gradual, and usually three or four days are required for the cellulitis to develop fully. Salient clinical findings of anaerobic cellulitis are: abundance of gas, foul odor, practically no skin changes or swelling, no pain and very little toxicity. On the other hand gas gangrene may be evident within a few hours of a given injury; the patient becomes extremely toxic; he suffers from severe pain, marked swelling and discoloration of the skin; appear a characteristic sweetish odor permeates the patient's surroundings and a moderate amount of gas is present in the tissues. (Gas in tissue may be visualized first in the roentgenogram.) Fortunately gas gangrene is much less frequent than the benign anaerobic cellulitis. Nevertheless, there is always the potential danger that some of these cases will develop gas gangrene.

Nightingale (35) divides this disease into four groups: (1) acute fulminating gas gangrene, (2) gas gangrene of the muscle, (3) gas abscess and

(4) subcutaneous gas infection. In his opinion, only the first two groups should be called "gas gangrene." The latter two should be classified as wounds with gas infection and should not be included in the statistics of gas gangrene. Sewell *et al.* (42) advocate the following diagnostic criteria: (1) positive clostridium-welchii culture (or vibrio septique) (2) spreading infection (3) gas in the tissues, and (4) discoloration and edema of the involved structures. They suggest the term gas cellulitis or clostridium cellulitis to include mild or borderline cases.

ETIOLOGY

The micro-organism *clostridium welchii* (47) was reported in 1893 and 1900. Shortly thereafter the vibrios septique and bacillus oedematiens were described as contributing causative organisms.

As the study of gas gangrene progressed, many more organisms were isolated. At present there are about 20 species (37) belonging to the clostridia group. For practical clinical purposes, the chief micro-organisms causing gas gangrene in order of prevalence are the *clostridium welchii*, *oedematiens*, *septicum*, and *histolyticum*. The pathogenicity is due to the toxins given off by the clostridia. These virulent organisms may be found alone or in combination, and when multiple organisms are present the fatality rate is increased. The worst is the *clostridium histolyticum*, for which no effective antitoxin has yet been developed. Its proteolytic action on living and dead tissue is maximal. MacLennan (27) reports it to be 100 per cent fatal. It is never found in the benign "anaerobic cellulitis."

Anaerobic bacteria may be found as normal inhabitants of the intestinal tract of man and animals. Their spores are also very plentiful in cultivated and fecally contaminated soil. These bacteria have a low pathogenicity for man and exist as saprophytes. However if they are introduced into a wound containing devitalized tissue, they multiply rapidly and may prove fatal. Devitalized muscle is an excellent culture medium for clostridia.

The source of the bacteria causing gas gangrene is still an unsolved problem. Some authors (2) are of the opinion that the bacteria are prevalent in wet, cold weather and in manured soil. Such soil was found to be present in Flanders from 1914 to 1918 and from 1939 to 1940. Other authors do not believe the soil content to be an etiological factor. Wall (44) states there is no soil more contaminated than that of the Yangtze delta in the region of Shanghai however there

have been very few cases of gas gangrene in this area. The African and Middle Eastern deserts (27) showed practically no clostridia when troops were in movement, but as soon as these troops camped for any length of time the clostridia were plentiful.

It is believed that woolen clothes (2, 18, 30) may be an etiological factor inasmuch as sheep are a major source of anaerobic bacteria and in cold climates, where woolen clothing is required, the incidence of gas gangrene is usually increased. To prove this theory Macs examined wool, cotton, and silk clothing: some samples were dry-cleaned and steam-pressed the remaining samples were untreated. Gas-forming organisms were found in almost all of the woolen samples, whether cleaned or not. No organisms were found in cotton or silk. Anaerobic bacteria have been found in the clothing of soldiers in the Middle Eastern theaters of the present war. The incidence of gas gangrene in the Italo-Ethiopian War and the Middle Eastern and African campaigns, in which the soldiers wore cotton clothing, has been low compared to that on the European continent where woolen clothing was worn. In any given battle, the incidence of gas gangrene may be increased or decreased according to the type of wound sustained. Bullet wounds would not show as high an incidence of gas gangrene as would wounds from high explosives, shells, or bomb fragments.

TREATMENT

As mentioned heretofore, there has been little change in the incidence or mortality of gas gangrene during the last twenty-five years. Treatment may be surgical, serological, chemical, radiological, or any combination of the four. Unfortunately not many advocates of a given method are in accord as to the efficacy of that method or any combination of methods. Consequently practically the entire medical armamentarium has been tried, and it would seem almost impossible to credit any one method with cure.

Theoretically gas gangrene should be prevented by adequate surgery, but such is not always the case. Results (28) in the Middle Eastern theaters of war are not too satisfactory. Of 124 cases of gas gangrene, 64 had had prophylactic surgery. Of 17 cases of anaerobic cellulitis, 7 were treated surgically. It is possible that debridement as done in the battles of the Middle East was not as radical as that done in 1917 and 1918.

Adequate debridement (48, 49, 50) should be done as soon as possible in an effort to avoid the onset of gas gangrene. The limb should be im-

mobilized and the body kept warm but heat should not be applied to the affected area. Embarrassment of the circulatory system should be avoided. Tight dressings, packings, or casts should not be used. A sympathetic block is preferred whenever vasospasm is present. Hematomas should be excised to relieve tension. If possible, foreign bodies are removed. The incidence of contamination increases if the wound is deep and irregular. Wounds of this type should be left open with adequate drainage (37). Diseased muscle should be excised. Alfonso (1) recommends its removal by cautery or surgical diathermy, however there is no other evidence in the literature that removal by cautery is effective. Gas gangrene per se is not sufficient to warrant an amputation. On the basis of his experiences in North Africa MacLennan (29) states "It is, unfortunately still the constant endeavor of certain surgeons in the Middle East and elsewhere to amputate or attempt to amputate each and every case of gas gangrene of the extremities. Amputation should be done when the condition of the limb would require amputation, even were no gas present."

The mortality of gas gangrene was reported by the A.E.F. in France to be 48.15 per cent. Millar reported a mortality of 49.7 per cent in 567 cases collected from civilian life. Coleman and Bennett (8) collected 41 cases of which 7 were treated by amputation with no deaths. 6 had amputation plus serum with 1 death. Swan (43) reported 9 cases of gas gangrene in the battle of Dunkirk. Amputation was done in 4 and an incision followed by the use of hydrogen peroxide serum, and sulfanilamide was made in 5. All 9 patients recovered. Fifteen cases of anaerobic cellulitis were treated with serum and sulfanilamide and the results were good.

The value of gas-gangrene serum still remains undetermined. Statistical clinical evidence is meager (5, 38, 50). In many cases in which it was used the dosage was either under or above the recommended one. Qvist (36) states that the mortality was 18 per cent when serum was used and 50 per cent when it was not used. Ghormley (13) reports a mortality of 13.4 per cent when serum was used and 44.5 per cent when it was not used. MacLennan reports that of 8 patients treated with serum, 2 (25 per cent) died and of 58 treated with serum and sulfonamides, 19 (33 per cent) died. The National Medical Research Council advocates the use of serum. However Kelly and Dowell (22) state that in their experience patients with diabetic gas gangrene do better without serum.

Sulfonamide therapy is used locally orally or both ways. Experimental and clinical evidence (40, 42) is not very encouraging. Of all the sulfonamide derivatives used sulfathiazole and sulfadiazine have shown the best results. Using neoprontol sulfanilamide, and sulfapyridine Hendricks (23) reports a mortality of 89.5 per cent in guinea pigs. Hawking (17) found that the local use of sulfanilamide sulfapyridine sulfaguanidine and sulfadiazine was not effective whereas the results with sulfathiazole were fair. Sandusky and Meleney (39) and Hac (14, 16) believe that the results in animals would be better if the drug were given within two or three hours of the development of gas gangrene. It was not effective when gas gangrene was permitted to become well established.

The use of sulfonamide drugs has not influenced the incidence of gas gangrene. The Bulletin of the United States Army Medical Department states that the prophylactic local and general use of sulfonamides has not prevented wound infection. The National Medical Research Council (Meleney, 32) reports that the use of sulfonamides prevents systemic invasional infection and thereby lowers the mortality rate. MacLennan states that of 43 patients who were given adequate doses of the sulfonamide drug, 22 developed gas gangrene. In his series of 28 cases treated with sulfonamides the mortality was 19 per cent. However he is optimistic with regard to the use of serum and sulfathiazole combined. In a second report of 44 cases of gas gangrene with a 30 per cent mortality MacLennan attributes the results to good surgery and intensive chemotherapy. Lyons (25) believes that there is a distinct trend away from local sulfonamide therapy. Sulfasuxidine therapy in wounds of the buttocks is indicated in order to eliminate organism contamination of the intestines.

The successful use of irradiation in gas gangrene was first described by Kelly and Dowell in 1928 (21). However experimental evidence (in animals) for the continued use of irradiation has been poor. Weed *et al* (45), Erb and Hodes (12) and Caldwell and Cox (7) all report poor results in guinea pigs, mice, pigeons, and in experiments *in vitro*. Bisgard *et al* (3) using rabbits, report that irradiation provided protection against a lethal culture in from twenty-four to forty-eight hours. These authors believe that x rays produce an antitoxic substance which neutralizes the effect of bacterial toxins.

Contrary to experimental evidence clinical reports (9, 11, 21, 22, 41) have been favorable. Kelly and others believe there is a distinct differ

TABLE I—TYPES OF INJURY OR DISEASE

	Prophylactic irradiation of compound fractures, etc.	Gas cellulitis	Gas gangrene

ence between the results obtained in the treatment of animals and those obtained in the treatment of human beings. Anderson and Olin studied 71 cases, of which 63 did not receive irradiation and 43 terminated fatally a mortality rate of 68 per cent. Two of the 8 patients treated by irradiation died a mortality of 25 per cent. Coleman and Bennett (8) reported a mortality of 71 per cent with irradiation, death occurring in 10 of 14 patients.

It is well to remember that although the total number of cases reported by each author is comparatively small, Kelly and Dowell reported a mortality rate of less than 10 per cent for a group of 200 cases collected from all sources. They are of the opinion that irradiation is a must in the treatment of gas gangrene. Some surgeons question this remarkably low mortality rate and believe some of these cured cases to have been anaerobic cellulitis. However other surgeons have seen such dramatic results with the use of irradiation that they recommend prophylactic irradiation for all compound fractures. Bowen (4) reports on 40 cases treated prophylactically 2 of the patients developed gas gangrene but none died. Bowen states that his surgical colleagues believe that the average lesion heals faster and that there is less mixed infection with preliminary irradiation. Mowat (2) reports that with prophylactic irradiation there is a marked and rapid reduction in traumatic edema, and relief from pain within the first twenty four hours none of his cases developed gas gangrene. Keating and Davis (20) recommend the use of prophylactic irradiation.

SAN FRANCISCO COUNTY HOSPITAL SURVEY

A series of 145 cases which was observed over a ten-year period from 1934 to 1944 at San Francisco County Hospital was reviewed by the author. Gas gangrene was present in 55 cases and gas cellulitis in 8, while prophylactic irradiation against gas gangrene was given in 82 cases. The gas-gangrene series was divided into two groups, those seen from 1934 to 1937 and those seen from 1937 to 1944. In the first group surgery was the

TABLE II.—PROPHYLAXIS

Total Cases	82	8	55

dominant therapeutic measure, but beginning with 1937 radiation therapy and sulfonamide drugs were added. During the latter period, some of the surgeons were so impressed with the results of irradiation that they requested that all compound fractures be given prophylactic irradiation. Consequently from 1937 to 1943 another group was treated with surgery and irradiation as the prime therapeutic measures.

In the majority of the 145 cases, the primary cause of the disease was trauma. There were several patients with diabetes, arteriosclerosis, and post surgical gas gangrene. (The initial injuries or diseases are listed in Table I.)

Prophylaxis was as follows:

Prophylactic surgery was done in combination with radiation therapy on 32 of the 82 patients having compound fractures, etc. surgery was done in combination with serum, sulfonamides, and radiation therapy on 25 surgery was done in combination with serum and radiation therapy on 15 and surgery was done in combination with sulfonamides and radiation therapy on 10. Two patients developed gas gangrene but the irradiation was continued and they recovered.

Prophylactic surgery alone was performed on 3 of the 8 patients with gas cellulitis, surgery was performed in combination with sulfonamides on 2 surgery was performed in combination with serum and sulfonamides on 1 and surgery was performed in combination with serum, sulfonamides, and irradiation on 2.

Prophylactic surgery alone was done on 15 of the 55 patients with gas gangrene surgery was

done in combination with serum on 10 surgery was done in combination with radiation therapy on 1 surgery was done in combination with sulfonamides on 4 surgery was done in combination with serum and sulfonamides on 5 surgery was done in combination with serum sulfonamides and radiation therapy on 2 surgery was done in combination with serum and radiation therapy on 1 serum alone was given to 2 sulfonamides alone were given to 3 and no prophylactic treatment was given to 12 (The prophylactic treatment in all three series is listed in Table II.)

With regard to the thirteen patients with gas gangrene who were seen in the period from 1934 to 1937 (including the 3 patients who entered the hospital in extremis) surgery alone was performed on 6 surgery was performed in combination with serum on 5 surgery was performed in combination with radiation therapy on 1 and serum alone was given to 1.

With regard to the 42 patients with gas gangrene who were seen in the period from 1937 to 1944 (including the 4 patients who entered the hospital in extremis) surgery and irradiation were the chief therapeutic measures. Surgery was done in combination with serum on 3 patients surgery was done in combination with roentgen irradiation on 5 surgery was done in combination with serum and sulfonamides on 4 surgery was done in combination with serum sulfonamides and roentgen irradiation on 10 surgery was done in combination with serum and roentgen irradiation on 6 and surgery was done in combination with sulfonamides and roentgen irradiation on 5 (Details of therapy and results are listed in Tables III, A and B.)

Thirty two of the 42 patients (1937 to 1944) were given serum as part of the treatment (a therapeutic dose of serum was given to 28) 17 (53 per cent) recovered of the 15 who died, 13 had been given a therapeutic dose. Sulfonamides were used in 28 instances and were given locally to 5 patients 14 (50 per cent) recovered. Although the drug was given early and in amounts that were adequate the derivatives were changed from day to day. Of the 35 patients who were given roentgen irradiation, 23 (66 per cent) recovered. The irradiation was given to the amputation stump of 17 12 of these recovered. Irradiation therapy was given to the involved area of the other 18 patients and 11 of these recovered. In 3 fatal cases, irradiation had been given as a last resort when the patients were in extremis. It is noteworthy that in 5 cases with recovery, irradiation was the only therapeutic agent used in combination with surgery. In addition to sur-

TABLE III A—TREATMENT AND RESULTS

(Thirteen cases of gas gangrene seen at San Francisco City and County Hospital, 1934 to 1937)

Surgery and radiation therapy	1	—	—	1
Serum	—	1	—	1
Total Cases	4	6	3	13

gery the combination of irradiation and sulfonamides was used in 24 cases with 11 fatalities, irradiation was given without sulfonamides in 11 cases with 1 death and sulfonamides were given without irradiation in 4 cases with 3 deaths. (Treatment and results are listed in Tables III A and B.)

It should be noted that during the period from 1934 to 1937 there were 3 patients who entered the hospital in extremis and during the period from 1937 to 1944, there were 4 patients who entered the hospital in extremis. Their condition was so critical that they would have died no matter what form of therapy was tried. Some died of other causes, such as fractured skull ruptured liver or spleen and carcinoma. Although these patients may have had a concomitant gas gangrene this was not the primary cause of death and therefore, their deaths should not be classified as gas-gangrene fatalities.

DISCUSSION

The problem of gas gangrene remains unsolved. The incidence and mortality have not changed appreciably since World War I, despite the fact that during the interval between wars the potency of sera has been doubled and sulfonamide drugs have been introduced.

Authors are agreed on the fundamental principle that early adequate débridement must be done in order to prevent gas gangrene. Amputation continues to be one of the most effective methods of combating the disease. However this is indicated only when there is extensive tissue destruction or when the circulation is impaired or lost. Kelly believes that extensive débridement or amputation should not be done during the acute toxic phase of the disease.

Results obtained by the use of serum either as a prophylactic or therapeutic agent are confusing. Very few clinical series appear in the literature.

Clinical results before and since sulfonamide therapy came into common use do not substantiate the effectiveness of these drugs as suggested by experimental work. Of all the sulfonamides, sulfathiazole and sulfadiazine are most effective. However local use of the drugs has failed to lower the incidence of infection. The best results obtained thus far are reported by MacLennan; he cites a 30 per cent mortality. He believes the lowered mortality rate to be due to good surgery and intensive chemotherapy.

In experimental gas gangrene, penicillin (15-24) was found to be far superior to the sulfonamides. McKnight *et al* (31) report a case of gas gangrene treated with penicillin with excellent results, after all other methods had failed. However more experimental and clinical investigations are indicated before penicillin is universally adopted.

It is difficult to explain the poor results obtained with experimental irradiation as the results are good clinically. The mechanism of irradiation is not fully understood. Bisgard's conclusions merit serious consideration. He and his associates found the protective factor produced by irradiation to be highest after from twenty-four to forty-eight hours. He thinks that this protective agent is probably a proteolytic enzyme which is released when the highly sensitive leucocyte is subjected to irradiation. Results obtained in almost all inflammatory lesions confirm this experimental evidence, namely that most inflammations will respond to irradiation within from thirty-six to forty-eight hours.

Although it was rather difficult to evaluate the effectiveness of radiation therapy in percentages

because of the many variable factors involved—such as the different types of therapeutic measures and combinations of these measures used—it is the opinion of staff surgeons and radiologists that irradiation had been very beneficial and was a decided factor in both the lower mortality rate and the rapidity of recovery in the gas-gangrene cases treated at San Francisco County Hospital.

In some instances, response to irradiation was so dramatic that the surgeons insisted upon prophylactic irradiation for all compound fractures.

During the last few years, controversy has arisen regarding the combined use of sulfonamides and irradiation. Kelly and Dowell are of the opinion that they are antagonistic. Buschke and Cantil (6) in reporting on the treatment of post-operative parotitis, state that when sulfonamides and irradiation are used there is a decided increase in the number of cases with suppuration. It is impossible to evaluate accurately the use of sulfonamide therapy in the San Francisco County Hospital series because of the fact that many derivatives were used and these derivatives were often changed from day to day; in addition, there were intervals wherein no sulfonamides were used at all. However when sulfonamides were used, the dosages were adequate. In some cases, in spite of the intensive chemotherapy which was immediately given, gas gangrene was evident within from one to three days.

It is obvious that little progress has been made in eliminating this disease. Inasmuch as gas gangrene may increase in incidence as the allied armies advance on the Continent and in other theaters of the war we should work together for unification of therapy in the study of gas gangrene and thus benefit from our experiences and those of others.

The experiences of any one physician in treating gas gangrene are limited. Even in large institutions the number of cases seen is relatively small. However institutions in large cities, and at the present time medical organizations in the armed service forces, have an unparalleled opportunity to carry out a systematic investigation as to the relative values of the various therapeutic measures.

The following briefly outlined plan is suggested as an approach to the further over-all study of gas gangrene in an effort toward unification of the existing therapeutic measures. The ideal place for execution of such a plan might be in the armed services where the incidence of gas gangrene is higher than in civilian life.

It is recommended that a Central Committee composed of (1) a surgeon (2) a radiologist and

(3) a bacteriologist assign a course of treatment to several different hospital units. Within each hospital unit there could be a similar qualified Local Committee under direct supervision of the Central Committee. Inasmuch as adequate surgical débridement still remains the method of choice in combating this disease all units should have competent surgeons skilled in the art of débridement. In addition to the usual surgery one team could give all patients polyvalent serum in adequate doses (from 60,000 to 100,000 international units). A second team could use surgery, sulfanilamide crystals given locally (sulfanilamide is more soluble than sulfathiazole) and sulfathiazole given systemically. A third team could use surgery serum and sulfonamides. A fourth team could use surgery and penicillin. A fifth team could use surgery and radiation therapy. A sixth team, surgery, sulfathiazole, and irradiation and a seventh team surgery penicillin, and irradiation. It is obviously not necessary to stress the importance of supportive care no matter what method of therapy is attempted.

If such a plan were to become effective within a comparatively short time sufficient data could be collected and statistics compiled to evaluate properly the best method of treating gas gangrene. In all fairness to the patient, whether military or civilian gas gangrene should be treated in a thoroughly scientific manner.

SUMMARY

1. The incidence and mortality of gas gangrene have not shown any appreciable change since World War I.
2. The etiology is discussed.
3. The importance of early diagnosis and treatment of gas gangrene is reviewed.
4. Surgery still remains the choice therapeutic agent. However results obtained recently with irradiation and chemotherapy point to better results in the future provided closer co-operation is maintained between the surgeon radiologist and bacteriologist.
5. The results at the San Francisco County Hospital show a decided improvement with irradiation, and to a lesser extent, with the use of sulfonamides.
6. Prophylactic irradiation was given to 82 patients, of whom 2 developed gas gangrene and recovered with further irradiation. Although we may not draw definite conclusions from these figures, the future of prophylactic irradiation is thought-provoking.
7. A plan for the unification of therapeutic methods is suggested and briefly outlined.

The author wishes to express his sincere appreciation to Dr. R. R. Newell, Professor of Radiology Stanford University Medical School, for giving so generously of his wider experience, and for his guidance, criticisms, and thoughtful co-operation, in the preparation and completion of this study. He also wishes to thank Dr. T. E. Albers, Medical Superintendent, San Francisco County Hospital, for granting permission to review the medical records. (The cases used in this series were from both the Stanford Medical School and the University of California Medical School services at the San Francisco County Hospital. Many of these cases were given treatment by the author while he was on the Radiological Service at this hospital.)

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Johnstone, D. F.: Cavernous-Sinus Thrombosis Treated with Penicillin. *Lancet* Lond. 1945 248

Before the days of sulfathiazole and penicillin recovery from cavernous-sinus thrombosis was quite exceptional. This case report deals with a nineteen-year-old woman who recovered from this condition following treatment with penicillin. The original lesion was a small boil to the left of the tip of the nose which went on to edema of the nose, the forehead and both eyelids. She was admitted with a white count of 18,000 cells per cubic millimeter she was very sick and had a slight proptosis. She was put on doses of sulfathiazole 1 gm. every four hours. By the third day the temperature had fallen but her general condition had deteriorated she was comatose and had severe proptosis with papilledema of both eyes. After six days her condition still showed no improvement and penicillin was started. She was given a total of 500,000 units in three days and marked improvement was noted immediately although there was still swelling of the lids and both eyeballs were immobile. A blood culture was not taken.

She became somewhat drowsy and complained of headache and nausea, but there were no signs of meningitis and her white count was 10,000 per cubic millimeter. Ten days later penicillin was resumed and she was given 100,000 units twice a day for three days. There was an instant response and all her signs and symptoms disappeared except slight proptosis and occasional diplopia but the headache became more pronounced and a lumbar puncture was done which showed clear fluid under normal pressure and an occasional lymphocyte. An electroencephalogram was taken which showed a delta discharge in the left frontal lobe and as it was feared that she might have a left temporal lobe abscess an exploration of the left frontal lobe was done, but the result was negative. Recovery followed in a few weeks.

Penick, R. M., Jr.: Preauricular Sinusitis; Diagnosis and Treatment. *Semin. M J* 1945 38 103.

The congenital nature of preauricular sinuses is emphasized by a constant association with an external dimple which is present from birth. The presence of these epithelial sinuses is made evident only when infection supervenes. Then the clinical picture will depend largely upon the depth to which the preformed structure extends. The clinical course is variable. In some instances there are sharply defined episodes, in others there is chronic involvement accompanied by ulceration of the skin.

Fig. 1: The probe inserted in the external opening emerges where the abscess has broken through the skin behind the tragus.

The presence of the small congenital dimple or pit at the anterior edge of the ear is characteristic and should immediately suggest the diagnosis. The recurring nature should serve to differentiate it from tuberculous and fungus infections. Sebaceous cysts are frequently found behind the ear but rarely anterior to it.

Treatment consists in elimination of the infection first and excision of the epithelial lined tract afterward. The latter can usually be done under local anesthesia. A complete cure can be expected if all of the abnormal structure is removed.

NOAH D. FABRICANT M.D.

Ungley H. G. and Suggitt, S. C.: Fractures of the Zygomatic Tripod. *Brit J Surg.* 1944, 31 287

Fourteen cases of fracture of the zygomatic tripod are reported and some aspects of the clinical signs and symptoms, x ray findings, and treatment of these fractures are discussed. In all of these cases operations were performed either by the temporal or canine fossa approach. Inhalation anesthesia, administered by means of an intratracheal tube with oral pack was used in all cases. Local infiltration of the canine fossa was found to be a useful adjunct.

The clinical features of fracture of the zygomatic tripod are flattening of the facial contour palpable fracture line infraorbital nerve injury diplopia

hemorrhage into the maxillary sinus, unilateral epistaxis, surgical emphysema of the face, and difficulty in closing the jaws.

The most useful x ray view is the mentonasal, such as is used to demonstrate the auxiliary antra. The main points to note are the degree of comminution of the anterior wall of the antrum, the degree of impaction and telescoping of the zygoma into the cavity of the antrum, the associated opacity of the antrum, and the separation in the vicinity of the zygomaticofrontal or zygomaticotemporal synostosis.

The characteristics of the fracture vary according to the site and direction of the blow and may be classified into 3 groups. Blows from the front result in a double vertical fracture line, and cause the intervening block of bone to be driven directly backward. Blows from the anterolateral aspect are the more common and they cause the zygoma as a whole to be driven posteriorly and medially into the antrum, the fracture line passing through the weakest point, in the region of the intraorbital foramen. Blows from the nasal or anteromedial aspect, cause the anterolateral portion of the maxilla together with the zygoma to be driven backward and laterally and a large part of the orbital floor is carried in the same direction.

Prompt surgical treatment is indicated before the fractured fragments lose their mobility. Elevation by the temporal route has the advantage of a clean approach through an area removed from the site of injury but some fractures are not reducible by this method, or if the fragments are replaced they will not remain in position after the elevating force is removed, because of comminution of the bones, particularly of the wall of the antrum. A ray evidence of comminution of the anterior antral wall, or a long period of delay between the time of injury and operation contraindicates elevation by the temporal route. The canine-fossa approach has the advantage that the fracture is exposed to view and however great the impaction, deformity or comminution, reduction of the fragments can be achieved and maintained. It has the disadvantage of exposing the fracture through a potentially infected oral cavity, which makes it necessary to delay operation if dental sepsis is present. Fixation can be obtained by wiring, simple impaction, wedging with one of the loose bone fragments, or by the use of a bone graft. External fixation may also be used but was not found necessary in these cases.

EYE

Blake, P. M. Injuries to the Eyes or to the Intracranial Visual Paths in Air Raid Casualties Admitted to Hospital. *Brit. J. Ophth.*, 1945, 29

Blake discusses injuries to the eyes and to the intracranial visual paths resulting from air raids in casualties admitted to hospitals and summarizes the findings as follows:

Of 8,833 persons exposed to within 100 feet of the explosion in 480 high-explosive bomb incidents, 0.75

per cent suffered injuries to the eyes or to the intracranial visual paths. Forty four per cent of the eye casualties lost the sight of one or both eyes or lost some vision. Eighty per cent of the eye casualties resulted from flying debris. Fifteen per cent of 66 casualties (10 individuals) in this series suffered from ocular injuries or injuries to the intracranial visual paths as a result of fractures of the vault of the skull or of the orbital bones. In this series of cases no eye injuries were caused by direct impact of the blast wave.

Direct injury to the eyes as well as fractures of the skull with consequent injury to the eye itself or to the intracranial visual pathways may result from bomb splinters, the flame of the explosion, secondary missiles (grit, sand, dust, and glass) and from direct injury by falls.

The actual number of serious eye injuries occurring at a distance of more than 100 feet from the fallen bomb was very small.

JOSUUA ZUCKERMAN, M.D.

Thorpe, H. E.: Nonmagnetic Intraocular Foreign Bodies. *J. Am. M. Ass.*, 1945, 27, 97

The author discusses the treatment of nonmagnetic intraocular foreign bodies. The increased employment of unskilled inexperienced personnel the accelerated industrial war effort the relative laxness in protective and preventive measures as well as the use of poorer quality hammers, chisels, and hatchets in civilian life has resulted in a larger number of nonmagnetic intraocular foreign-body cases in combat and in industry. Nonmagnetic foreign bodies comprise those made of manganese steel alloys, copper, brass, lead, aluminum, or wood. Magnetic foreign bodies can be differentiated from nonmagnetic by the history of injury examination of the working tools, examination of fragments removed from the face or other exposed parts of the body in explosion cases, and the use of the Berman locator. The Vogt and Comberg methods provide a simple x ray technique. Tridimensional concept of the foreign-body position is obtained with stereoscopic x-ray films and a localizing shell. Air injection in Tenon's space is of assistance in diagnosing double perforations.

Conservative therapy is advisable if more than three intraocular foreign bodies are present.

Prompt removal of intraocular foreign bodies with the aid of the endoscope is recommended. Groping in the vitreous with any instrument should be avoided.

The eyeball should never be mutilated simply to remove a chemically inert foreign body although glaucoma may be a later development in some of the cases.

Detachment of the retina should be treated.

The fellow eye should always be examined for the presence of another foreign body lodged after the same or a previous accident, and for the onset of sympathetic ophthalmia. To avoid infection it is necessary to remove foci of infection maintain asepsis and patency of the lacrimal passages, and to use foreign proteins and sulfonamide drugs.

JOSUUA ZUCKERMAN, M.D.

Cordes, F. C.: Metastatic Carcinoma of the Choroid. *Am. J. Ophth.*, 1944, 27, 1355

About 250 cases of metastatic carcinoma of the choroid have been reported in the literature, arising, in order of frequency from the breast, lungs and bronchial alimentary tract, prostate, and rarely from the thyroid, liver ovary and parotid gland. X ray therapy of the eye was reported three times with some improvement in vision but of course no effect upon the life expectancy of the patient.

A thirty-one year-old woman with bilateral metastasis to the choroid from a scirrhous carcinoma of the breast was seen by the author. One eye was enucleated and the diagnosis confirmed by microscopic examination. When the second eye became involved x-ray irradiation was employed. The tumor disappeared and left a lighter colored area in the fundus with fine dustlike clumpings of pigment and a suggested relative scotoma corresponding to the area. The central visual acuity remained 20/30. There was a recurrence of the tumor after fourteen months, with regression after further irradiation. The vision remained normal until the death of the patient, twenty three months after the first irradiation.

While the ultimate prognosis for life in these cases remains hopeless the use of radium or x rays on the metastatic growth in the eye may serve to retain useful vision for the patient, and should therefore be considered as a palliative measure. The earlier the choroidal metastasis is observed the better the chance of retaining useful vision by this means. It is of interest to note that although this patient received 3,315 roentgens at the time of the original irradiation and 3,356 roentgens at the time of the recurrence, no lens opacities had developed up to the time of death eight months after the second irradiation.

While the author believes radium or x rays will give identical results he prefers x rays because they can be given more readily and they are more universally available.

WILLIAM A. MAJOR, M.D.

EAR

Malone, P. W.: Aviation Deafness. *Arch. Otolaryng.*, 1944, 40, 468

The author reviews the basic experimental work on behavior of the eustachian tube during changes of altitude and presents personal observations showing the occurrence of a localized dip at the 4,000 frequency following two- and four hour flights in an open cockpit airplane. Such dips had disappeared

on the following day. In contrast, the result of repeated exposures is reflected in the audiogram of a pilot with 8,000 flying hours mostly in open cockpit planes which show a permanent hearing loss through the 1,000 to 4,000 frequencies. The use of a tight fitting helmet and headphones by the student in open cockpit planes prevented the localized hearing loss almost entirely. The permanent loss is regarded as being due to chronic accumulative fatigue of the end organ.

An audiogram is presented demonstrating the effect on the hearing of aviation pressure deafness or acute sero-otitis media. This produces a low tone deafness up to the frequency of 1,000 double vibrations in contrast to the deafness to noise which first appears at the 4,000 frequency.

JOHN R. LINDSAY, M.D.

NECK

Fox, J. R.: Paralysis of the Larynx; An Early Sign of Recurrence Following Radical Mastectomy for Carcinoma, with a Report of 6 Cases. *Arch. Surg.*, 1944, 49, 388.

When hoarseness occurs following mastectomy for carcinoma of the breast the possibility of metastasis must be considered. In each of the cases presented in this group there was a period following mastectomy during which the patient enjoyed complete symptomatic freedom from disease. This period varied from fourteen months to twelve years. The patient's well-being was then suddenly interrupted by changes in the voice, described as persistent hoarseness or huskiness. There were also intermittent weakness of the voice, a tendency for the voice to crack, and a nonproductive cough, unaccompanied by any evidence of infection of the respiratory tract. Dyspnea was severe in 1 patient and was experienced on exertion by the others. In each instance, however, it was the laryngeal disturbance which caused the patient to consult her physician.

Part of the drainage of lymph from the breast has been satisfactorily traced to the chain of nodes surrounding the recurrent laryngeal nerve. Metastasis, therefore, may be from a cancerous breast on the same or on the opposite side. There are three generally accepted lymphatic pathways of homolateral drainage which the author mentions.

Contralateral involvement, interestingly, is not the exception, since it occurs with almost the same frequency as paralysis of the same side.

Six cases are presented with the laryngeal findings.

JOHN F. DILLON, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Holmes, W., Hight, W. B., and Seddon, H. P.: Ischemic Nerve Lesions Occurring in Volkmann Contracture. *Brit. J. Surg.* 1944, 31: 59.

Six cases of established Volkmann's contracture of an upper limb in which there was gross damage to the peripheral nerves from the ischemia were studied in detail and reported. This study was undertaken in an effort to determine the etiological part played by the nerve lesion in the deformity and whether or not the nerve lesion is amenable to treatment. In 4 of the 6 cases the radial pulse had been completely absent for a period varying from several hours to a week following the injury and much reduced in volume thereafter. In 1 additional case the arteriogram showed the site of arterial injury to be at the wrist, below the level at which the pulse is palpable. Oscillometer recordings demonstrated a serious impairment of the circulation below the level of the arterial injury and a slight reduction of oscillations immediately proximal to it.

Skin-temperature readings were of no value in the late differential diagnosis of ischemic contracture and peripheral nerve lesions since either a serious vascular lesion or a peripheral nerve lesion is sufficient to abolish reflex vasodilatation in the affected cutaneous zone. However skin temperature readings taken early after the onset of the lesion would differentiate a vascular from a nervous lesion since the denervated area would vasodilate. Only after an interval of about twenty-one days after denervation does the reflex vasodilatation fail to occur.

Arteriography in all cases gave a demonstrated obliteration of the main artery at the site of the injury with evidence of an established collateral circulation. The latter was sufficient to prevent gangrene; however there was a distinct deficiency of small vessels in the areas of muscular necrosis. These findings emphasize that Volkmann's paralysis is produced by damage to a main artery and the resulting widespread vascular spasm including even remote vessels. The vascular spasm included vessels proximal to the site of injury as well as distal to it.

Testing of electrical activity of the paralyzed muscles should easily distinguish between simple denervation and ischemic necrosis. The former gives the typical reaction of degeneration responses, while the latter fails to respond at all. However two major difficulties cause this method to fail in the differential diagnosis. Edema of the skin and subcutaneous tissues, often present in these deformities, causes percutaneous stimulation of muscle to be extremely unreliable. Also necrosis of muscle may be patchy and the response of non-necrotic parts to electrical stimulation might make it appear that the entire muscle was responding and was therefore unaffected by ischemia.

Three possible explanations of the extensive sensory and motor paralysis accompanying the muscular contracture are discussed: direct trauma to the nerves at the time of injury; nerve injury secondary to contracture of the muscles; and last, injury to the nerve caused by ischemia of the nerve itself. Pathological findings in the nerve trunks indicated to the authors that the latter mechanism was the cause of the nervous paralysis. The remarkable atrophy and induration of the main nerve trunks in the ischemic zone was quite unlike any condition seen after an uncomplicated nerve division or Wallerian degeneration. One case in which the ischemic zone did not extend to the most distal part of the limb, had markedly atrophic and fibrotic nerve trunks in the ischemic zone but more distally the trunks were of normal size and showed Wallerian degeneration.

Pathological study of the nerve trunks in the contracted limb revealed the nerve changes to vary from simple Wallerian change to complete destruction of all cells in the nerve. The latter nerve infarction is widely distributed in and near the necrotic muscle. Another ischemic change of great importance found was endoneurial collagenization. This is irreversible, and fiber regeneration through Schwann tubes obliterated by thickened endoneurial collagen is impossible.

In all of the cases reported in this article, there has been recovery in the radial muscles of the forearm except in distal muscles which were necrotic. Sensory and pseudomotor recovery had taken place in the distribution of the superficial radial nerve. Only little evidence of recovery in the median and ulnar nerves was noted. Thus it may be concluded that in severe cases of ischemic contracture there is not only a failure of recovery in the necrotic muscles, but likewise in muscles which are not necrotic but are supplied by nerves damaged by ischemia, and also that sensory recovery may be very imperfect. This failure of recovery is due to irreversible ischemic change in the nerves. There was no evidence from these cases that any form of treatment has any significant effect on the recovery of nerve function. The aim in dealing with Volkmann's contracture must be to prevent it.

HENRY A. SHENKIN, M.D.

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Shannon, E. W., and Morgan, C. W., Jr.: The Cerebrospinal-Fluid Protein in Metastatic Brain Tumors. *England J. M.* 1944, 311: 874.

Forty three cases of metastatic brain tumor have been studied with particular reference to the protein content of the cerebrospinal fluid. No constancy of the protein content was present, although almost all the cases show an increase above normal. In a com-

parison of the total protein content of the cerebrospinal fluid in primary brain tumors, no satisfactory differentiation could be perceived.

The conclusions resulting from this study were that the protein contents of the lumbar cerebrospinal fluid alone does not differentiate a metastatic neoplasm from a primary brain tumor.

HOWARD A. BROWN, M.D.

Fig. 2 Sketch of operative field to show the appearance of the caudal sac and its contents. The irregular spacing of the sacral roots which come off at right angles from the elongated conus medullaris is evident.

SPINAL CORD AND ITS COVERINGS

Walker, A. E.: Dilatation of the Vertebral Canal Associated with Congenital Anomalies of the Spinal Cord. *Am. J. Roentg.* 1944, 51: 571.

Four cases of dilatation of the spinal canal resulting from congenital anomalies of the spinal-cord structures have been reported. Three of these cases have been associated with myelodysplasia, and the fourth resulted from a vascular anomaly of the cord.

The dilatation of the canal has been discovered by roentgenograms in addition to the clinical neurological findings. The first 3 cases were in the lower portion of the spine and in the first instance the condition was associated with a lipomatous mass involving the nerve roots in the second, third, and fourth sacral root areas. The myelodysplastic condition found here consisted of a single trunk in the lumbosacral region from which the lumbar and sacral nerves were given off instead of a cauda equina. The sacral canal was markedly dilated and the condition was associated with a spina bifida occulta. The neu-

Fig. 1 Roentgenogram of the lumbosacral spine showing the enlargement of the spinal canal in the sacral region and the spina bifida occulta of the first sacral vertebra. The interpedicular distances measured: thoracic 1: 31 mm., 2: 23 mm., lumbar 3: 27 mm., 4: 28 mm., 5: 29 mm., 6: 31 mm., 7: 33 mm., and sacral 1: 42 mm.

rological symptoms consisted of mild impairment of the function of one lower extremity with urinary disturbances beginning in adolescence. The later symptoms were the result of tension upon the spinal cord associated with a greater growth of the vertebral column and relief was obtained by sectioning the adhesions binding the conus medullaris to the sacral sac.

The second case was associated with a splitting of the spinal cord in the upper lumbar region amounting to a diplomyelia or a diastematomyelia.

The third case was in the cervical spine with marked dilatation of the canal, and operation revealed a hydromyelia and diastematomyelia. In this case the choroid plexus was found to be in association with the cystic cavity which was encountered.

The final case was associated with deformity of the left foot, previously diagnosed as anterior poliomyelitis, and subsequent urinary difficulties in a fifteen-year-old boy. Bloody spinal fluid was encountered and x rays revealed marked widening of the lower thoracic and upper lumbar spinal canal. Operation revealed an angioma and an aneurysm of the spinal cord. Slow improvement followed.

The author believes that dilatation of the spinal canal as demonstrated by roentgenograms may indicate either a congenital anomaly or an erosion from tumor, but accurate differentiation is not possible by this means alone.

HOWARD A. BROWN, M.D.

Elliott, P. A. and Kramer, M.: Brachial Pain from Herniation of Cervical Intervertebral Disc. *Lancet*, Lond., 1945 248 4.

This article is from a military hospital for head injuries and concerns 8 cases of pain in the upper limb which, on clinical and radiological grounds, were thought to be due to herniation of the sixth cervical intervertebral disc. There was partial verification of 3 of the cases by a pantopaque myelogram. However none of the patients were operated on they were all treated by conservative management.

On the assumption that these were cases of herniated discs in the neck region the clinical findings were recorded. It was found for instance that neck movements to the side of the lesion aggravated the pain. The pain was accentuated by coughing and sneezing and at the same time it was relieved by mechanical traction on the head. In this series, most of the hypaesthesia and numbness was felt in the index finger and the thumb for in all of the cases in question it was presumed that the seventh cervical nerve root was affected. In 1 case there was pain on the inside of the hand and arm to the ring and little finger and this was thought to be due to secondary scalenus spasm. Trauma did not seem to be an essential part of the clinical picture. The uniform distribution of the pain was down the back of the shoulder down the back of the arm to the radial border of the forearm, and sometimes into the upper pectoral region. There was limitation of movement in the neck and the most constant reflex finding was a reduced or absent triceps jerk with hypaesthesia of the thumb and index finger. ADRIEN VERBOOGHEM M.D.

MISCELLANEOUS

Hamilton, J. E. Whitcomb, B. B. and Woodhall, B.: Penicillin in the Treatment of Surgical Infections of the Central Nervous System. *Surg Clin. N. America*, 1944, 24 1389.

Twelve cases of surgical infection of the central nervous system which have been treated by penicillin

are reported. These include 6 brain abscesses, 4 epidural abscesses, and 2 cases of traumatic meningitis. One patient succumbed and this was a case of brain abscess secondary to a suppuration of the lungs.

The authors stress the fact that penicillin passes through the choroid plexus into the cerebrospinal fluid only in minute traces, and certainly not in therapeutic amounts. Previous experimental studies by Pilcher have shown that the intravenous use of penicillin is ineffective in the treatment of staphylococcal and pneumococcal meningitis in dogs, whereas a marked beneficial effect resulted when the drug was administered intrathecally.

Further emphasis is laid upon the fact that adequate surgical treatment must be combined with proper dosage and administration of penicillin. In the case of brain abscess, improvement is noted during the early stage of cerebritis when penicillin is used parenterally. Once the abscess is formed, however penicillin is of little benefit unless it is used locally in the abscess cavity and when it is so used adequate dosages running up to 50,000 or more units, are necessary.

The removal of infected bone, or at least of sequestrae is a necessary adjunct if satisfactory results from the use of penicillin are to be expected.

One patient, who had evidence of brain abscess secondary to a lung abscess, has been reported as cured—which is unique as cases of this type have almost invariably been considered fatal in the past.

In meningitis, penicillin must be used intrathecally in order to obtain therapeutic effects in the subarachnoid system and dosages have averaged from 10,000 to 50,000 units daily. It has been shown that the therapeutic level of penicillin remains in the subarachnoid system as long as twenty-four hours after the injection of 10,000 units.

The lumbar route is advised for injection, with occasional use of the posterior cistern or even the ventricle in obstructive cases.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Gershon-Cohen, J. and Dalbridge R. E.: Pseudarthrosis, Synchondrosis, and Other Anomalies of the First Ribs. *Am. J. Roentg.*, 1945 53 49.

During the course of routine roentgenological examinations of the chest many anomalies may be seen with or without pertinent symptomatology. It is important for the roentgenologist to be able to recognize anomalies that have no referable symptomatology as well as those that do.

Anomalies of the first rib occur most frequently and asymmetry or failure of ossification of the anterior aspect of the rib is observed most often. Failure of ossification according to Todd, is due to compression of the subclavian vessels during the embryological development. Bifid first ribs are rare. Some times the entire rib is absent.

Synchondrosis generally is seen in the posterior third of the rib. At times it is almost impossible to distinguish a synchondrosis from a pseudarthrosis. Absence of history of injury, no evidence of callus, smooth edges along the plane of dissolution, and no abnormal bone changes are in favor of a synchondrosis. Spontaneous rib fractures can occur with no history of injury. However in such instances some tenderness is present as well as a lump caused by callus formation. Pseudarthrosis may be due to muscle pull of the scalenus anticus. Bilateral fractures with resultant pseudarthrosis are rare.

Although most anomalies of the first rib are of no clinical significance, it is important to differentiate between a congenital synchondrosis and fracture pseudarthrosis.

Graustman R. L., and Goldman M. L.: Tuberculous of the Breast. Report of 9 Cases Including 2 Cases of Coexisting Carcinoma and Tuberculous. *Am. J. Surg.* 1945 67 48.

Approximately 1 of every 100 breast conditions is tuberculous mastitis. The portal of entry of the tubercle bacillus is often difficult to determine. In various of the breast may occur by one of the following routes: through the milk ducts, by way of the nipple through abrasions of the skin by direct extension from the lungs and chest through the blood stream and through the lymphatics. In most cases, however the tubercle bacillus is carried to the breast by retrograde extension through the lymphatics from tuberculous cervical axillary or mediastinal lymph nodes. Trauma may be an etiological factor in rare instances.

In the series reported the average age of the patient was thirty-five years. Although pregnancy and lactation are predisposing factors in the etiology of tuberculosis of the breast, 30 per cent of the women with mammary tuberculosis were single, and approximately 4 per cent of all cases occurred in males.

For practical clinical purposes the disease is considered as being of 2 types—a primary type in which there is no demonstrable evidence of tuberculosis elsewhere in the body and a secondary type in which evidence of tuberculosis elsewhere is present.

Based on gross pathological findings the cases fall into 3 groups:

1. *Nodular* The tubercle, usually situated in the connective tissue enlarges to form a lump from 2 to 10 cm in diameter. As the condition progresses caseation and suppuration occur and sinus formation may develop.

2. *Sclerosing* This form of the disease is characterized by excess fibrosis and is seen more often in older people.

3. *Typical* This includes rare types of lesions such as obliterating mastitis and intraglandular cold abscess.

Most patients are in apparent good health. The earliest symptom is usually a painless lump in the breast. An early complaint is a discharging sinus (in from 20 to 30 per cent of cases). Enlarged axillary nodes are present in about half of the cases. The physical findings depend on the stage of the disease and the type of the underlying pathological condition.

A differential diagnosis is to be made from simple pyogenic mastitis, degenerated gumma, actinomycosis, and carcinoma. When no sinus formation is present, a differential diagnosis is to be made from carcinoma, benign fibroepithelial tumors, chronic cystic mastitis, gumma, plasma-cell mastitis and traumatic fat necrosis.

In primary cases the prognosis is good. In secondary cases the prognosis depends on the primary focus and its activity and extent. The generally accepted treatment of choice is excision.

Guinea-pig inoculation in addition to the usual bacteriological study of chronic discharging breast sinuses is advisable. For the proper surgical management of all suspicious breast lesions the use of the frozen section is essential. SAMUEL KADW M.D.

Adair F. B., and Herrmann J. B.: Primary Lymphosarcoma of the Breast. *Surgery* 1944, 16 836

The authors review the literature on primary lymphosarcoma of the breast, and conclude that only 3 of the reported cases satisfy their requirements for classification as localized primary lymphosarcoma of this organ.

In the past twenty years 445 patients with benign tumor and 650 patients with malignant tumor were seen on the breast service of the Memorial Hospital, New York, New York. There were only 5 cases of primary localized lymphosarcoma. The patients were white women in the fourth or fifth decade of life. The time which elapsed between the discovery of the tumor and the institution of sur-

Elliott, F. A. and Krenser, M.: Brachial Pain from Herniation of Cervical Intervertebral Disc. *Lancet*, Lond., 1945 248 4.

This article is from a military hospital for head injuries and concerns 8 cases of pain in the upper limb which, on clinical and radiological grounds, were thought to be due to herniation of the sixth cervical intervertebral disc. There was partial verification of 3 of the cases by a pantopaque myelogram. However none of the patients were operated on they were all treated by conservative management.

On the assumption that these were cases of herniated discs in the neck region the clinical findings were recorded. It was found, for instance, that neck movements to the side of the lesion aggravated the pain. The pain was accentuated by coughing and sneezing, and at the same time it was relieved by mechanical traction on the head. In this series, most of the hypaesthesia and numbness was felt in the index finger and the thumb for in all of the cases in question it was presumed that the seventh cervical nerve root was affected. In 1 case there was pain on the inside of the hand and arm to the ring and little finger and this was thought to be due to secondary scalenus spasm. Trauma did not seem to be an essential part of the clinical picture. The uniform distribution of the pain was down the back of the shoulder down the back of the arm to the radial border of the forearm and sometimes into the upper pectoral region. There was limitation of movement in the neck and the most constant reflex finding was a reduced or absent triceps jerk with hypalgesia of the thumb and index finger. ADRIEN VERBURGHEM M.D.

Hamilton, J. E., Whitcomb, B. B. and Woodhall, B.: Penicillin in the Treatment of Surgical Infections of the Central Nervous System. *Surg Clin. N. America*, 1944, 24 1389.

Twelve cases of surgical infection of the central nervous system which have been treated by penicillin

are reported. These include 6 brain abscesses, 4 epidural abscesses, and 2 cases of traumatic meningitis. One patient succumbed, and this was a case of brain abscess secondary to a suppuration of the lungs.

The authors stress the fact that penicillin passes through the choroid plexus into the cerebrospinal fluid only in minute traces, and certainly not in therapeutic amounts. Previous experimental studies by Pflüger have shown that the intravenous use of penicillin is ineffective in the treatment of staphylococcal and pneumococcal meningitis in dogs, whereas a marked beneficial effect resulted when the drug was administered intrathecally.

Further emphasis is laid upon the fact that adequate surgical treatment must be combined with proper dosage and administration of penicillin. In the case of brain abscess, improvement is noted during the early stage of cerebritis when penicillin is used parenterally. Once the abscess is formed, however, penicillin is of little benefit unless it is used locally in the abscess cavity and when it is so used adequate dosages, running up to 50,000 or more units, are necessary.

The removal of infected bone, or at least of sequestrum, is a necessary adjunct if satisfactory results from the use of penicillin are to be expected.

One patient, who had evidence of brain abscess secondary to a lung abscess, has been reported as cured—which is unique as cases of this type have almost invariably been considered fatal in the past.

In meningitis, penicillin must be used intrathecally in order to obtain therapeutic effects in the subarachnoid system and dosages have averaged from 10,000 to 15,000 units daily. It has been shown that the therapeutic level of penicillin remains in the subarachnoid system as long as twenty-four hours after the injection of 10,000 units.

The lumbar route is advised for injection, with occasional use of the posterior cistern or even the ventricle in obstructive cases.

Adair, F. E., and Herrmann, J. B.: Primary Lymphosarcoma of the Breast. *Surgery* 1944, 16 836.

The authors review the literature on primary lymphosarcoma of the breast, and conclude that only 2 of the reported cases satisfy their requirements for classification as localized primary lymphosarcoma of this organ.

In the past twenty years, 4,415 patients with benign tumor and 6,519 patients with malignant tumor were seen on the breast service of the Memorial Hospital, New York, New York. There were only 5 cases of primary localized lymphosarcoma. The patients were white women in the fourth or fifth decade of life. The time which elapsed between the discovery of the tumor and the institution of sur-

gery was from two to four weeks. The right breast was involved in 4 of the 5 patients. The lesion was single in 4 patients, and in 1 patient there were 2 lesions. The lesion was located in the upper and outer quadrant of the breast in 4 of the 5 cases. The tumor mass ranged from 1 to 4 cm in diameter. In 1 case there was nipple retraction, and in 3 skin attachment or dimpling. X-ray examination of the chest in 3 cases revealed an absence of pulmonary or mediastinal involvement.

All the patients except the one who had undergone a local excision of the tumor elsewhere were treated by surgery alone. Radical mastectomy was performed in 3 cases, and a simple mastectomy with axillary dissection was done in the fourth case. The patient who had a local excision of the tumor elsewhere was given high-voltage irradiation to the area of excision but not to the axilla.

The pathological diagnosis in 3 cases was reticulocell sarcoma, and in 1 case, follicular lymphosarcoma (Brill Symmers disease). The section of the tumor excised elsewhere was interpreted as consistent with lymphosarcoma. No involvement of the axillary nodes was found in any patient.

The 3 patients treated by radical mastectomy are alive and free of disease after periods of seven years, three years and six months, respectively. The patient treated by local excision and deep x-ray therapy is also alive and free of disease one and one half years after the surgical procedure. The patient treated by simple mastectomy is alive three months following surgery.

HEART AND PERICARDIUM

Cooper, F. W., Stead, E. A., and Warren, J. V.: The Beneficial Effect of Intravenous Infusions in Acute Pericardial Tamponade. *Ann. Surg.* 944, 20-8.

Opinions differ as to whether or not the intravenous administration of physiological saline solution is beneficial in patients with acute pericardial tamponade resulting from a stab wound of the heart or great vessels. The elevated venous pressure in pericardial tamponade is said to be produced by the damming up of blood due to obstruction to the venous inflow to the heart. When the venous pressure exceeds the pressure of the obstruction the blood can flow into the heart. Thus, survival in pericardial tamponade is dependent upon elevation of the venous pressure. This rise in venous pressure is produced by a combination of vasoconstriction and redistribution of blood in the vascular system. Because the venous inflow to the heart is then dependent on the cardiac output, the amount of venous distention which can be caused by damming up the venous inflow to the heart is limited by the diminished cardiac output and venous filling. These experiments were undertaken to determine whether or not increase of the blood volume with intravenous fluids to raise the venous pressure might be beneficial in pericardial tamponade.

Acute pericardial tamponade was produced in 5 dogs by introducing physiological saline solution from a reservoir into the closed pericardial sac. The pressure required to produce severe symptoms varied in different animals from 12 to 22 cm. of water but it was quite constant for the same animal. After the pericardial pressure necessary to produce severe symptoms was determined, a rapid intravenous infusion was given to increase the blood volume. The dogs were then again subjected to pericardial tamponade and it was found that they could withstand from 92 to 146 per cent greater pressure. Two experiments were conducted with a closed system to duplicate the conditions of pericardial tamponade in human patients. Severe tamponade was produced and the tube leading from the pericardium was clamped. In both of these dogs there was distinct improvement with the intravenous administration of 300 cc. of saline solution.

From a theoretical standpoint, it appears that improvement in the circulation under these circumstances would depend upon the ability of the pericardium to stretch and allow an adequate cardiac filling with the increased venous pressure. In these experiments such stretching appeared to occur and the increased pericardial pressure was more than compensated for by the increased venous pressure.

Saline infusions were administered to 3 patients admitted to the hospital with traumatic pericardial tamponade, and in each case the arterial pressure rose and the patient became more rational. At operation the wounds in the heart and pericardium were found to have remained sealed, in spite of the rise of arterial pressure. This form of therapy may serve as a useful adjunct in the treatment of pericardial tamponade either by aspiration or operation, and in certain selected patients may restore the circulation to an adequate level without aspiration or operation.

JOHN L. LINQVIST, M.D.

ESOPHAGUS AND MEDIASTINUM

Clark, D. E.: Trans thoracic Esophagogastrostomy for Carcinoma of the Middle Third of the Esophagus. Report of a Successful Resection. *J. Surg.* 945, 3-65.

Trans thoracic resection for carcinoma of the lower third of the esophagus with esophagogastrostomy has become a well standardized procedure which can be performed with considerable success.

Progress in the surgical treatment for carcinoma of the middle third of the esophagus has not kept pace with that of the lower third or with other thoracic tumors. Until recently all of the carcinomas of the middle third were resected by the method used and developed by Torek. Although this procedure fulfills the principles of good cancer surgery it is not entirely satisfactory, in that esophagogastric continuity is not re-established.

The cervical esophagostomy may be connected to the abdominal esophagostomy or gastrostomy by means of an anterior thoracic esophagoplasty or if

such is unsuccessful, a rubber tube. The rubber tube connection is an unending source of complaints. The tube frequently becomes dislodged or plugged and is almost constantly leaking. Many ingenious methods have been proposed for anterior thoracic esophagoplasty utilizing skin tubes, stomach, gastric tube, jejunum colon, and a combination of jejunum and skin tube. Most of these operations require multiple operative procedures and are quite difficult to perform. Fifty-eight cases were operated upon by Ludwig by the combined methods. He used a segment of jejunum for the lower part and a skin tube above.

Construction of skin tubes either with or without jejunal transplantation usually requires numerous operative procedures. Fistulas develop and strictures occur at the mucocutaneous junctions. Both of these distressing complications are difficult to handle. More than 50 per cent of anterior dermatoesophagoplasties are never completed. Most of the patients dying of recurrence before the skin tube is completed.

Recently Garlock described a method for reestablishment of esophagogastric continuity after resection of a carcinoma of the middle third of the esophagus. In his case he anastomosed the fundus of the stomach over and above the arch of the aorta. This procedure is a definite advance in the surgical treatment of carcinoma of the middle third of the esophagus. It not only affords radical removal of the tumor but eliminates artificial swallowing devices and anterior thoracic esophagoplasties. The success of Garlock prompted the author to employ a similar procedure in a man who had a carcinoma involving the middle and lower thirds of the esophagus.

For the sake of brevity only the most salient points are mentioned here. Under positive pressure ethylene-oxygen-ether anesthesia, a long incision was made over the course of the seventh rib beginning at the costochondral junction anteriorly and extending backward to about the lateral edge of the recti-spinae muscles. At this level it was carried upward for a distance of about 8 cm. The entire seventh rib was removed subperiosteally and the fifth, sixth, eighth, and ninth ribs were transected. The phrenic nerve was crushed just above the diaphragm. The mediastinal pleura was incised along the medial edge of the aorta from the diaphragm to the arch of the aorta. By means of blunt and sharp dissection the esophagus was mobilized from the posterior mediastinum. Both vagus nerves were divided above the diaphragm. The mediastinal pleura was incised above the arch to the supra-sternal notch. The esophagus above the level of the tumor was easily freed. By careful blunt dissection the involved esophagus was freed from beneath the arch of the aorta and from the trachea and left main bronchus. A 16-cm. radial incision was made in the diaphragm from the periphery toward the esophageal hiatus. The left phrenic artery was divided and ligated. The greater omentum was divided close to the stomach down to near the pylorus. This divi-

sion was made so that the gastro-epiploic vessels remained in the omentum. The ligation was carried down to where the first branch of the right gastro-epiploic artery came off to the stomach. In order to remove the lymph node metastases it was necessary to divide the left gastric artery near the celiac axis. The upper and lower branches of the left gastric artery were divided and the gastrohepatic omentum incised near the liver. The lesser omentum, the left gastric artery and the accompanying nodes of the latter were completely excised from the lesser curvature of the stomach. The stomach was divided just below the cardioesophageal junction and the distal end infolded with two rows of linen sutures. The proximal end was covered with a rubber glove. The mobilized esophagus was then drawn out through the opening in the mediastinal pleura above and to the left of the arch of the aorta. The stomach, which appeared viable, was easily brought up into the chest and an anastomosis made between the end of the esophagus and an opening in the fundus of the stomach. The first posterior row of sutures was placed about 6 cm. above the upper limits of the tumor. An umbilical tape was placed around the esophagus 3 cm. above these sutures and tied twice the second tie being a slipknot. The lower two-thirds of the esophagus was now removed and the anastomosis completed. The elongated stomach was sutured to the pericardium and pleura over the aorta as far as the diaphragm which was closed with interrupted sutures around the prepyloric portion of the stomach. Five grams of sulfathiazole crystals were sprinkled in the operative field. A de Pezzer catheter was inserted posterolaterally through the ninth interspace for pleural drainage.

The patient's postoperative course was complicated by a chylothorax. Because of the anatomic location of the thoracic duct, the injury of it may be more frequent in resecting lesions of the middle third of the esophagus than in operations for lesions of the lower third. Since the protein content of chyle is from 2 to 4 gm. per cent depletion of the protein stores will occur very rapidly unless adequate replacement is promptly instituted. Plasma should be given or the chylous fluid if sterile may be administered intravenously.

Roentgenological study after the ingestion of barium, made about four months after the operation revealed a marked obstruction of the stomach where it passed through the diaphragm. The excursion of the left leaf of the diaphragm was full. It appeared that the obstruction was due to regeneration of the phrenic nerve and recovery of the muscle tone of the diaphragm. In view of this, it is a question if it would not be better to excise a long segment of the phrenic nerve to insure permanent paralysis of the left leaf of the diaphragm.

The patient got along quite well for three and one-half months, then he began to lose weight and strength. A cough developed and his appetite failed. His condition gradually became worse and he died five months after the operation.

In the author's case the greater and lesser curvatures were ligated to the prepyloric region and only the blood supply which comes from the prepyloric segments of the right gastric and right gastroepiploic arteries was left. Despite this extensive sacrifice of blood vessels the circulation of the stomach remained adequate.

Ligation of the blood supply to such an extent presumably may result in necrosis of the stomach in some cases. Therefore, a safer procedure would be to leave the right and left gastroepiploic vessels attached to the stomach, and divide and ligate the omentum distally. If this were done, complete removal of the left gastric artery and its accompanying nodes could be performed with very little fear of impairment of the gastric circulation. Since the lymph nodes along the lesser curvature of the stomach are intimately associated with the lymphatic drainage of the esophagus, and usually contain metastases, their removal is definitely indicated.

MISCELLANEOUS

Barrett, N. R.: Hemothorax; Notes and Observations. *Lancet*, Lond., 1945 248 3

Hemothorax comprehends the chief part of traumatic thoracic surgery. The author's notes are based upon experience gathered at the thoracic surgical unit of a war hospital and at a coast hospital.

Hemothorax has 3 immediate harmful effects—blood loss, pleural cavitation, and the development of a space-occupying lesion in the chest. In some cases the blood is absorbed spontaneously with no residual effects, but more generally the bloody effusion acts as a retained foreign body and pathological changes continue. Fibrin is laid down and this forms localized pockets, as well as an envelope around the lung. The fibrin layer on the lung prevents re-expansion, and healing results in contractures of the chest wall, diaphragm or mediastinum.

The bleeding may come from the lung or the parietes. Bleeding from the lung may be profuse, but it is usually short-lived. Persistent or delayed bleeding is generally due to wounds involving the chest wall or diaphragm. The diagnosis is usually not difficult, but can be confused with atelectasis or diaphragmatic hernia. In the absence of pleural adhesions, shifting of the mediastinum is a late sign and indicates extensive bleeding. In a case of moderate bleeding with mediastinal shift, the lung is probably held out by pre-existing adhesions. Common symptoms are shock, pain, dyspnea, and fever.

The treatment is varied, but the author bases his therapy on the basis that (1) total expansion of the lung should be obtained at the earliest possible moment (2) a hemothorax is a foreign body in a vital serous cavity, (3) there is no way of predicting in which cases the blood will not be absorbed (4) infection may occur at any time, and (5) there is little hemostatic value in leaving the blood in situ, and aspiration is likely to start a fresh hemorrhage only

if a high negative pressure is produced. Repeated aspirations may be very effective if started within twenty-four hours. In many cases this is the only therapy needed. If hemorrhage is still going on the patient should be given a transfusion and the bleeding point secured by operation. If bleeding has stopped, but a massive hemothorax is present and cannot be emptied by aspiration, a thoracoscopic aspiration may be done. If the hemothorax has clotted or bleeding persists for weeks, the chest should be opened the pleura emptied, and decortication of the lung performed. If a foreign body of considerable size is present in addition to the hematoma, a thoracotomy is done. In cases of combined thoracoabdominal wounds care should be taken not to overlook a hemothorax. THOMAS F. THORNTON, JR., M.D.

Coleman, F. P.: Traumatic Hemothorax; Decortication in the Treatment of the Chronic Uninfected Type. *Arch. Surg.* 1945, 50 14.

The respiratory disability associated with the later stages of wounds of the thorax incurred during war is a real problem. Infection is primarily responsible for the disability in the majority of cases, however or ganization of blood within the pleural cavity untended by sepsis is not uncommon and often leads to an even greater degree of respiratory invalidism.

When blood escapes into the pleural cavity it apparently undergoes early formation of a clot. The views expressed by Elliott offer an explanation for what appears to be the absence of clotting of blood within the pleural cavity. The author stated that the effused blood very rapidly passes through the clotting process, but that the coagulation is interfered with by the respiratory movements so that the fibrin is to a considerable extent whipped out of the blood. If bleeding into the pleural cavity is slow the blood is readily deprived of fibrin by the movements of the diaphragm and the heart. The pleura is irritated by the blood, and an effusion is poured out. The blood free of fibrin mixes with the effusion, resulting in a fluid hemothorax, which does not undergo formation of a clot on removal from the pleural cavity. The fibrin is usually deposited in a dependent location. If bleeding into the pleural cavity is rapid, sufficient agitation may not be present to bring about defibrination of the blood, and a solid hemothorax results. Other factors which favor formation of a massive clot within the thorax are extensive destruction of tissue and retention of foreign bodies within the pleural cavity.

The pleura is able to cope with the deposit of fibrin in a small hemothorax. The associated effusion is either aspirated or absorbed. In such cases no functional incapacity results. On the other hand, deposition of fibrin accompanied by a process of organization may be sufficient to lead to the formation of dense pleural adhesions. The mobility of the diaphragm, thoracic wall, and lung is restricted. In such cases a routine roentgen film may reveal only slight haziness over the base of the lung, however the limitation of the motion of the diaphragm is readily ob-

vious during fluoroscopy and a deposit of fibrin may be identified in the costovertebral sulcus by suitable lateral roentgenograms of the chest. The mechanism of the disability associated with the organization of a large hematoma within the pleural cavity is obvious. The thick wall of the hematoma fixes the pleural surface of the ribs, and thereby interferes with the normal widening of the intercostal spaces during inspiration. Organized fibrous tissue contracts, drawing the ribs closer together and the normal longitudinal curves of the ribs are lost. The involved hemithorax becomes flattened and immobile. The diaphragm, when involved loses its function entirely. The involved portion of the lung is usually normal but it cannot perform its function when it is confined in a fibrous encasement.

The temporary disability associated with uncomplicated hemithorax has been attributed to the organization of fibrin within the pleural cavity. Pain and shortness of breath are the primary symptomatic manifestations. Detailed roentgenograms and fluoroscopic examination of the chest, as a rule, reveal some fixation of the diaphragm and a deposit of fibrin in the costovertebral gutter. The symptomatic manifestations and the disability associated with obvious chronic organized hemithorax do not require a great deal of comment. Patients with this complication are unfit for military duty. They are chronic invalids. A low-grade fever is usually present, and even in the absence of infection the temperature may reach a daily level as high as 102 F. There is distinct pallor to the skin and frequently secondary anemia is present. Dyspnea on exertion and pain in the involved side of the chest are common symptoms. The hemithorax is flattened and immobile. There is compensatory emphysema of the uninvolved lung. The compensatory activity of the contralateral lung exaggerates the deformity produced by the chronic organized hemithorax. In the treatment of chronic traumatic uninfected hemithorax the surgical approach is governed somewhat by the site of the formation of the clot. The blood clot usually assumes a dependent position within the pleural cavity lying in the costovertebral gutter and overlying the diaphragm.

Access to this region is readily accomplished by making a posterolateral incision and the pleural cavity is entered through the seventh or eighth intercostal space. The wall of the hematoma is encountered on division of the intercostal muscles and the parietal pleura. A cleavage plane between the wall of the hematoma and the pleura may be developed with ease, because of the fact that these structures are bound together by only a light net work of vascular and fibrous tissue. The wall of the hematoma is freed from the adjacent structures by blunt dissection the surgeon working away from the thoracic wall and lung. The index finger or a blunt gauze dissector has proved satisfactory for this procedure. It is possible to mobilize a large hematoma in this manner without disruption of its physical characteristics. After the lung, the diaphragm and

Technic of Decortication of Lower Lobe

Fig. 1. Illustrations of the operative procedure.

the thoracic wall have been freed of the hematoma, the underlying pleura may be observed to be practically normal. It is not thickened and it still has a somewhat smooth and glistening appearance. The previously constricted diaphragm and lung will function in a normal manner with removal of the fibrous encasement. In a clotted hemithorax of less than three weeks' duration the cleavage plane between the pleura and the wall of the hematoma is not sharply demarcated. At this stage the wall of the hematoma has not become well organized and there is persistence of the edema of the adjacent pleura. Early removal of the deposit of fibrin does not permit the ready re-expansion of the lung which is so admirably demonstrated when this structure is freed of a well organized hematoma. BENJAMIN GOLDMAN M.D.

Johnson, E. K., Wolff W. L., and Lambert, A. V. S.: Sulfonamide Therapy in Clean Thoracoplasty Cases. *Ann. Surg.* 1945 121: 120.

The authors report concerns 83 patients who were subjected to 303 clean thoracoplasty operations. The modern thoracoplasty operation averaging 3 ribs at each stage was performed in almost every case and generally silk technique was used. There were 3 series of operations (1) those done after sulfonamides were applied locally (2) those done after sulfonamides were given orally and those done on patients who had received no sulfonamides (controls).

The first series consisted of 97 operations, done after the sulfonamides were applied locally to the thoracoplasty wounds, an average of 4.7 gm. being

used per operation. No known toxic reactions occurred and there was no evidence of delayed wound healing. Twenty of the 97 cases were reviewed to determine the excess wound fluid and an average of 328 cc. was aspirated from each. Blood and wound fluid levels were found to be between 3.0 and 5.0 mgm. per cent within eight hours. The blood level was down in forty-eight hours and the wound fluid level was down in ninety-two hours. The sulfadiazine levels rose and fell less rapidly than the sulfanilamide levels.

The second series numbered 39 operations, after which the patients received sulfonamides orally for three or four days. There were 4 reactions. All wounds healed by the tenth postoperative day. Six of 10 cases analyzed for excess wound fluid were found to have about 135 cc. each. Levels from 5.0 to 9.0 mgm. per cent were present in both the blood and wound fluid while the drug was given. The wound fluid level was usually slightly higher. Sulfadiazine levels lagged as in the first series.

The third series was composed of 67 operations which were not accompanied by sulfonamide therapy. All wounds healed promptly. Fifteen cases

were examined for excess wound fluid serum, and in the 8 cases which developed excess serum it averaged 110 cc.

Delay in healing was not noted in the 3 series, although excess fluid was more likely to form if the sulfonamides were applied locally.

The incidence of pyogenic infections in the entire series was 5.4 per cent. All bacterial contaminants were cocci. There was no great difference between the controls and the treated cases.

It does not appear logical to subject clean thoracoplasty wounds to routine prophylactic sulfonamide therapy as only a small portion become contaminated and even a smaller number develop infections. The occurrence of excessive wound fluid with the local application and the occasional toxic reaction with the oral administration of sulfonamide therapy seem more hazardous than the infrequent severe infections. If contamination of the thoracoplasty wound is indicated by cultures the authors suggest the systemic use of sulfonamides. If gross contamination is present local plus systemic therapy may be employed.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Narando, M M Pierson J C. McNeer G and Pack, G T: *The Economic Value of Peritoneoscopy* Ann Surg 1945 131 185

Peritoneoscopy as a diagnostic procedure has been known to clinicians since 1901

At the Memorial Hospital, New York the chief interest in this field has been in the determination or recognition of the inoperability of various intra abdominal neoplasms. One can frequently appreciate the inoperability of some cancers by this examination, but on the contrary the resectability can never be ascertained with any degree of certainty. If this fact were universally known the limitations of the instrument would be accepted and no extravagant claims for its use would be made. The recognition of metastases in the liver or carcinomatous implants on the parietal or pelvic peritoneum for example, would discourage any surgical attempt at removal of a gastric cancer.

The chief indication for its use is the attempted determination of inoperability in borderline cases when clinical evidence of such inoperability does not exist. If the criteria which determine inoperability are not fulfilled on peritoneoscopic study a celotomy should be done immediately and the tumor will then be found to be resectable or inoperable. This discovery of inoperability should not be listed as a failure for peritoneoscopy because it only confirms the well recognized limitations and handicaps of the method.

This relatively safe minor procedure will often prevent useless exploratory celotomies in patients who are poor surgical risks. The economic advantages to the patient and to the hospital are great.

Peritoneoscopy is generally indicated in the following conditions: intra abdominal tumors, particularly malignant tumors; cirrhosis of the liver; ascites of undetermined origin; tuberculous peritonitis; ectopic pregnancy; and lesions of the internal female genitalia. The procedure is contraindicated in acute inflammatory conditions of the abdomen; advanced cardiac or pulmonary diseases; and extensive peritoneal adhesions. The single death in this series occurred in a jaundiced patient.

Since January 1940 peritoneoscopy was employed upon 80 patients at the Memorial Hospital. Of these 26 had primary gastric cancers, 12 had cirrhosis of the liver, 7 had neoplasms of the gall bladder or liver and 6 patients with mammary cancer had peritoneoscopic visualization of their livers.

Of the 26 patients with carcinoma of the stomach who were subjected to peritoneoscopy the purpose of peritoneoscopy was satisfactorily fulfilled in 14 or 53.8 per cent. In 7 patients, metastatic cancer was found to involve the liver, parietal peritoneum or both, and in this group a major operation was

avoided. In 7 other patients whose gastric cancers were at first thought to be of questionable or borderline resectability the endoscopic findings did not contraindicate surgical exploration, which was undertaken and the cancers were removed. In 12 patients (46.1 per cent) the procedure was of little value.

Peritoneoscopy is of great value in the differential diagnosis between cirrhosis and malignant tumors involving the liver. In 9 of a group of 12 cases exploratory celotomy was avoided because of the fact that the correct diagnosis was easily established on peritoneoscopy.

HARRY W. FINE, M.D.

GASTROINTESTINAL TRACT

Saunders, W W: *Gastric Herniation at the Esophageal Hiatus. Permanent Foundation M. Eull* 945 1 1

Herniation of the stomach at the esophageal hiatus is the most frequent type of diaphragmatic hernia. As a rule it is incidental and symptomless but it may cause serious or even fatal bleeding ulceration with perforation, distressing nausea and vomiting as well as many other lesser complaints. The diagnosis of hiatus hernia may be suspected clinically when a patient complains of anginal pain worse after eating or when lying down in addition to other upper gastrointestinal symptoms. A ray study will usually show the lesion provided the proper supplemental maneuvers are utilized. These are roentgen examination of patients in the standing, supine, prone, and right oblique prone positions, with barium suspension in the esophagus. If this is not done some of the hernias which are reducible may be missed.

The type of hernia should be noted for the guidance of the surgeon who may undertake repair. If the esophagus is filled with barium mixture at the same time that the hernia is the relationship may be determined with the patient in one of the prone oblique positions. It is important to recognize those few cases in which the downward growth of the esophagus has not kept up with the caudal migration of the diaphragm because this forces a portion of the stomach to remain intrathoracic. These are not true hernias and should not be erroneously included in this group.

Of the 200 upper gastrointestinal examinations made during the past two years, 28 were found to be gastric hernias through the esophageal hiatus. In 20 of these 28 patients, the symptomatology could be explained only by the hiatus hernia, no other lesions being demonstrable. Nine of the patients had hernias which involved one third of the stomach, all the rest being small.

The often noted fact that size does not determine the presence or intensity of symptomatology held for this series, for 2 of the 4 patients without symptoms

had large herniations. In addition 80 per cent of these patients could be relieved by medical treatment and about 10 per cent had severe symptomatology which may require surgical intervention. The remaining 10 per cent had no symptomatology at all.

SAMUEL J. FOOTELOW M.D.

Fresman, H.: A Gastroscopic Control of the Treatment of Gastric Ulcer by Duodenal Feeding. *Brit. J. Surg.* 1944, 32, 3, 3.

The author makes a renewed attempt to popularize the method originally advocated and practiced by Einhorn in America and Ernest Young in London and consisting of duodenal feedings in order to provide a complete rest for the stomach and to limit its secretion to a minimum. Although roentgenography is still the standard method of choice in the diagnosis of an ulcer the author has found a number of ulcers on gastroscopy which were missed by the radiologist. This may have been accounted for by failure of the barium to fill the crater because the flow was already filled with slough of the mucus. Therefore, patients who present ulcer symptoms and in whom a negative x ray examination has been reported should be examined with the gastroscope, and the examination should be repeated subsequently before cessation of treatment is contemplated.

In 15 patients in whom duodenal feeding was carried out the average time required for healing was four weeks. This was confirmed gastroscopically. The types of chronic ulcer which respond most readily to the regime of duodenal feeding are (a) those of moderate or long duration without complications, (b) ulcers which have given rise to occasional hematemesis, and (c) early cases of penetrating ulcer.

Failures are usually due to (1) lack of co-operation by the patient, especially in the early stages of treatment. This lack of co-operation often includes surreptitious feedings (foods brought by relatives who believe they are being kind to the patient) (2) deep penetration into the pancreas and (3) an incorrect diagnosis, i.e., malignant ulcer or early malignant change in a chronic ulcer.

There is, of course, no direct evidence that duodenal feeding provides for a more permanent cure than when other methods of treatment are used but a breakdown of the old ulcer is far less likely because of the rapidity with which the original lesion heals under conditions in which this treatment is carried out.

It is advisable to keep the patient in bed for the first fortnight after treatment is begun. After this interval he is allowed up gradually. Many patients have carried on their work during treatment by duodenal feeding. Pain is absent in almost all cases within forty-eight hours of the start of the tube feedings. Rarely it may be necessary to give atropine hypodermically. If, however, pain persists after this short period, the diagnosis should be reviewed, for the possibility of deep penetration into the pancreas or malignant change in the ulcer must be considered.

As to the technique, preferably an Einhorn or Kyle's thin rubber tube No. 7 should be used. These two types are softer and more flexible than other types and are therefore less liable to irritate the pharynx. The tube is passed in the morning on a fasting stomach. It is proved to be in the duodenum if on attempting to aspirate with an attached hypodermic syringe, withdrawal of the plunger is difficult and the tube collapses as long as the withdrawal of fluid is easy. The tube still lies in the stomach. A glass container into which the food is placed is hung 3 ft. above the level of the head of the bed. To it are connected a rubber tube and a funnel, the distal end of the tube being connected by a glass tube to the duodenal tube. The following points should be observed: (a) the feeding should take from twenty to thirty minutes; (b) all food must be strained through gauze and given slightly warm; (c) before and after feedings a 10-cc. syringe of water followed by a syringe of air must be passed down the tube to keep it clear; (d) after feeding, the duodenal tube is disconnected, looped so as to occlude it, and fixed behind the patient's ear (A small spigot may be put in the end of the tube.); (e) the feeding apparatus must be cleansed with cold water after each feeding. The tube is retained for twenty-one days, it is then withdrawn and the patient is examined with the gastroscope. If healing is complete, the 'initial diet' is started; if not, the tube is replaced.

Nothing whatever enters the stomach. All food and medicine pass straight into the duodenum. Each feeding consists of 8 oz. of milk (dried milk can be used) plus any other substance such as arrowroot, eggs (or dried eggs) and lactose. Some patients cannot tolerate quite all of this quantity which is reduced accordingly. Seven feedings are given daily at two-hourly intervals, starting at 8 a.m. It is a good plan to alternate the preparations used in conjunction with milk. If constipation is present a suitable dose of cascara evacuant is given in the feeding. Vitamin C (ascorbic acid) 150 mgm. daily should also be added.

In very nervous patients a mixture of bromide and valerian given through the tube helps to allay any anxiety or mental stress, conditions which so very often accompany peptic ulceration. Occasionally excessive salivation may render the tube intolerable under these circumstances a hypodermic injection of atropine (gr. 1/50) once daily will overcome this difficulty.

The initial diet to follow the duodenal feeding immediately consists of a scrambled egg (or dried substitute) with toast and a little butter and a cupful of weak tea, with or without milk, but no sugar. For breakfast flaked boiled fish, sieved potatoes, and toast for lunch 2 teacupfuls of tea without sugar and a few plain biscuits in the afternoon and breast of chicken or rabbit, sieved potatoes, toast, junket, stewed prunes (sieved) and not more than ½ a tumblerful of water for supper. One hour before breakfast and lunch and on retiring, a tumbler

ful of hot water is offered. A gradual increase in the above diet is made until lean beef mutton, and other meat are included. No change in vegetables, however, should be made until two months have elapsed since the beginning of the treatment.

JOSEPH K. NARAT, M.D.

Carlaw, J.: Peptic Ulcer; A Study of the Number of Cases Treated in the Western Infirmary of Glasgow during Forty-Six years (1897 to 1942). *Glasgow M. J.*, 1944, 142: 183

In the last twenty years there has been an alarming increase of peptic ulcer, especially in the area of Glasgow, and particularly in men there were more duodenal than gastric ulcers. The incidence of gastric ulcer in women has long been noted to be much greater than that in men and to occur at an early age while the incidence of duodenal ulcer although less common has long been recognized as more frequent in men. The examination by means of x rays, the chemical analysis of the gastric contents, and the testing of the feces for blood are methods of examination that have for many years been giving increasing accuracy to the diagnosis of these cases. Since these methods have been perfected during and after the first Great War the hospital statistics of the last twenty years are far more important than those of earlier periods.

By means of a series of charts the author covers the hospital returns for admissions of peptic ulcer at the Western Infirmary of Glasgow for the period from 1897 to 1942, inclusive. Chart I gives the returns for gastric ulcer duodenal ulcer and hematemesis in men. It shows a marked increase in the frequency of ulceration, especially of duodenal ulcer in the last twenty years and remarkably low figures in the earlier years. By contrast, Chart II gives similar returns for women showing high figures for gastric ulcer mostly in younger women in the years from 1897 to 1907 with a gradual decrease from then on. This is no doubt related to the prevalence of chlorosis in those earlier years. In both these charts the relative frequency of gastric and duodenal ulcers may be considered to be more accurate in the later years. Even today in medical cases, in spite of modern methods, it is sometimes difficult to be sure whether the ulcer is gastric or duodenal. Forty years ago the possibility of a duodenal origin was just beginning to be appreciated. It is possible too that in the earlier years, cases diagnosed as gastritis or gastric catarrh were in reality cases of peptic ulcer. This may further explain the contrast between the later and the earlier years.

One might suspect that a larger number of patients being admitted to the hospital might explain the large figures of recent years, but the admissions to medical wards over the period only increased from about 1,500 in 1897 to about 2,300 in 1942 while the increase of admissions to surgical wards was much greater from about 4,500 to 11,500. Chart III shows the numbers for peptic ulcer (gastric, duodenal, and hematemesis) in medical wards for

men and women, a composite picture of Charts I and II. It shows again the preponderance of peptic ulcer in the early years and its comparative infrequency for the period from 1908 to 1924. The later extraordinary increase of duodenal ulcer is graphically shown. This chart corresponds with remarkable accuracy with Chart IV which gives the record of abdominal sections for perforated ulcer many of these cases undoubtedly having been in medical wards previously.

The first recorded abdominal section for perforation was done in 1897 it was a gastric perforation. The first operation for a perforated duodenal ulcer was done in 1900. Without doubt many perforations occurred and went untreated in those earlier years much as happened previously with appendicitis. The medical profession learned to diagnose perforation and the remarkable success of the surgeons in dealing with those cases led to their being sent to the hospital as soon as possible. We may therefore safely assume that the majority of these perforations have been surgically treated for the past twenty years.

Chart IV shows a tremendous and steady rise of perforations (gastric and duodenal) operated on from 31 in 1921 to the great total of 206 in 1941. The increase was accounted for mainly by the increase in duodenal cases occurring mostly in men. Although some hemorrhage and perforation some times occur in patients with no previous history there usually is a definite history of months or years sometimes of from twenty to thirty years or more, and the same chronic case may develop both of these serious complications. The experience of Alacrae an expert in abdominal surgery was that in his wards (Western Infirmary) 75 per cent of cases of duodenal perforations had a history of over three years symptoms and that 10 per cent had a history of over ten years symptoms. In the light of findings such as these the appearance of perforation or hemorrhage can scarcely be linked to some recent cause.

While this interesting study does little more than call attention to the prevalence of peptic ulcer and its rather appalling increase in recent years it invites considerable speculation as to the primary cause. No solution is as yet forthcoming. The close relationship between the ulcer and the presence of gastric juice has incriminated hydrochloric acid as a causal factor. The typical peptic ulcer is met with only at the lower end of the esophagus, in the stomach, in the first part of the duodenum and more recently in the jejunum at or near the stoma following gastrojejunostomy. The hydrochloric acid of gastric juice in at least the earlier stages of peptic ulcer is found to be higher than normal and this favors that assumption. The author is inclined to think that the primary condition is an erosion of the mucous membrane which is acted upon by the gastric juice, and this stimulates an excess of gastric juice, which causes, in fact, somewhat of a vicious circle. The problem to be solved would seem to be what causes these erosions?

General health, anemia, overfatigue and mental anxiety would be of resistance while heredity is a definite susceptibility. However, these factors do not explain the primary cause. In the case of a diet factor does not seem to provide an explanation. The author states "since the beginning of this century there has been wars, industrial stress and the strain of unemployment, and recently there has been the bombing of so many of our cities and these may have had an influence. But the contrast of the incidence of ulcers in men with that in women during recent years can hardly be explained by such causes as it would seem women have been exposed to these conditions as much as men. The author adds that the high incidence of perforation and the quite serious mortality from septicemia rather seem to be a reflection on the local treatment and would seem to indicate more after care. It is to be hoped that investigations which have been carried out by S. Wolf and H. S. Wolf (New York 1912) may help to solve the difficulties of determining some primary cause of this rather serious disease. Morris J. Saiter, M.D.

Walt on Sir J. Marsh H. C. J. Evans H. H. Tidy Sir H., and Others: Discussion on Treatment of Duodenal Ulcer. *Proc. R. Soc. Med. Lond.* 1934, 27, 3.

This report gives the views of several known members of the Royal Society of Medicine on the treatment of duodenal ulcer. Sometimes there is conflict but the crux of the discussion with regard to surgical treatment of the duodenal ulcer revolves about the choice of procedure between gastroenterostomy and gastrectomy. It is brought out that a type of surgical treatment that is effective in a kind of surgeon's hands may be ineffective in the hands of another. Moreover the social environment of each patient has a direct bearing on the case. Likewise the habitat of a locale produces differences in the character of the ulcer.

Dr. JAMES WALTON, president of the Section of Surgery, opened the discussion by warning the younger surgeons not to accept the written word without question but to find the truth for themselves. He said that this danger Walton is warning them against very strongly to be aware of and avoid. He said that in the determination of which he can conscientiously find his results to give the method of treatment. He said that immediately after the last World War, the results of the treatment were equal with what he said that he had found to be the best course of treatment. He said that Walton's views are based on the fact that he is a surgeon of study. He said that he had never said that "no man is fit to say that form of treatment is a cure cure. And that he said that he had found the best results in his own hands. There are a lot of different things that

It is a general conclusion that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem.

even of perforation is a sense evidence. He said that Walton asserts that the standard of comparison with the social position of the individual patient. Thus, a man in comfortable circumstances may be free of symptoms and be apparently cured on a diet and in a sheltered life while as the other man made upon a working man entail an entirely different set of conditions which would produce a different cure in his instance.

The discussion as to operative technique in England for uncomplicated cases is principally between gastroenterostomy and partial gastrectomy. In a few cases local excision with plastic procedure of the pylorus may be the method adopted. The balance between posterior gastroenterostomy and partial gastrectomy depends upon the frequency of gastric junctional ulceration after posterior gastroenterostomy. Walton calls attention to the many reports that have been published by continental surgeons and some from the United States showing an incidence of from 1 to 15 per cent. These reports, he believes, have undoubtedly influenced many English surgeons, but he said that with conditions quite dissimilar to those in the countries whence the reports are issued and where partial gastrectomy seems to be the rule.

Walton said that in his carefully chosen follow-up series the incidence has always been about 5 per cent and that these results have been constant. Moreover he said that while partial gastrectomy reduces the acidity to a greater degree it does not entirely remove the danger of this complication. In his series of 16 gastric junctional ulcers a partial gastrectomy had been previously performed in 12. There can be little doubt that of the two procedures partial gastrectomy is the more severe. While many series have been published with a very low mortality it must be remembered that the operations were performed by surgeons exceptionally skilled in this technique. In the hands of the general practitioner this technique would probably show a death rate of between 5 and 10 per cent, whereas with gastroenterostomy it should not be more than 1 per cent. Walton's conclusion is that in duodenal ulcer by posterior gastroenterostomy whether or not they be gastric stenosis and to serve partial gastrectomy for 10 per cent of cases that have ulcerated gastric junctional ulcer. Nevertheless, he would not feel able to determine the case which are likely to develop gastric junctional ulcer and to perform a gastric resection on them. He said that he knew he could control the acidity in the stomach but that they are probably cases in which the ulcer has been already healed and cases in which the ulcer is actually healing.

He said that Walton's conclusion is that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem. He said that Walton's conclusion is that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem and that the treatment of the duodenal ulcer is a difficult problem.

General ill health, anemia, overfatigue, and mental anxiety would lower resistance, while heredity might determine a susceptibility. However, these factors do not explain the primary cause. Diet, alcohol and tobacco do not seem to provide an explanation. The author states: Since the beginning of this century there have been wars, industrial stress and the strain of unemployment, and recently the added distress resulting from the bombing of so many of our cities, and these may have had an influence. But the contrast of the incidence of ulcers in men with that in women during recent years can hardly be explained by such causes as it would seem women have been exposed to these conditions as much as men. The author adds that the high incidence of perforation and the quite serious mortality from severe hemorrhage seem to be a reflection on medical treatment and would seem to indicate more after-care. It is to be hoped that investigations on the lines of those carried out by S. Wolf and H. S. Wolf (New York 1932) may help to solve the difficulties of determining some primary cause of this really serious disease. *M. THOMAS J. SALTER, M.D.*

Walton, Sir J., Marshall, C. J., Evans, H. Tidy, Sir IL and Others: Discussion on Treatment of Duodenal Ulcer. *Proc R Soc Med Lond* 1934 38 9

This report gives the views of several well known members of the Royal Society of Medicine on the treatment of duodenal ulcer. Sometimes these views conflict, but the crux of the discussion with regard to surgical treatment for duodenal ulcer revolves about the choice of procedure between gastroenterostomy and gastrectomy. It is brought out that a type of surgical treatment that is effective in a skilled surgeon's hands may be ineffective in the hands of another. Moreover the social environment of each patient has a direct bearing on the case. Likewise habitat or locale produces differences in the character of the ulcer.

Sir JAMES WALTON, president of the Section of Surgery, opened the discussion by warning the younger surgeons not to accept the written word without question but to find the truth for themselves. To counteract this danger Walton considered it essential for every surgeon to have a well organized follow up department in which he can conscientiously study his own results to prove his methods, if indicated. Immediately after the last World War Walton's hospital in London was equipped with what appears to be the first clinic of this sort in Great Britain. Walton's views are based on this twenty-five year follow up study. Since technical surgery is an art, he states, "no man is entitled to say that one form of treatment is alone correct. All that he can say is that it gives the best results in his own hands, others may find different methods more suitable."

It is generally conceded that the one indication for surgical interference is the failure of medical treatment. The presence of stenosis or hemorrhage

or even of perforation is in a sense evidence of this failure. Walton asserts that the standard of cure varies with the social position of the individual patient. Thus, a man in comfortable circumstances may keep free of symptoms and be apparently cured on a diet and in a sheltered life, whereas the demands made upon a working man entail an entirely different set of conditions which would prove inadequate for such an instance.

The decision as to operative technique in England for uncomplicated cases lies principally between gastric resection and partial gastrectomy. In a few cases local excision with plastic procedures upon the pylorus may be the method adopted. The choice between posterior gastroenterostomy and partial gastrectomy depends upon the frequency of gastrojejunal ulceration after posterior gastroenterostomy. Walton calls attention to the many reports that have been published by continental surgeons and some from the United States showing an incidence of from 3 to 35 per cent. These reports, he believes, have unduly influenced many English surgeons, who have to deal with conditions quite dissimilar to those in the continent, hence the reports are misused and where partial gastrectomy seems to be the rule.

Walton states that in his carefully controlled follow up result the incidence has always been about 4 per cent, although these results have been constant. Moreover he states that while partial gastrectomy reduces the acidity to a great degree it does not entirely remove the danger of this complication. In his own series of 176 gastrojejunal ulcers a partial gastrectomy had been previously performed in 12. There can be little doubt that of the two operations partial gastrectomy is the more severe. While many series have been published with a very low mortality it must be remembered that the operations were performed by surgeons exceptionally skilled in this technique. In the hands of the general practitioner this technique would probably show a death rate varying between 5 and 10 per cent, whereas with gastroenterostomy it should not be more than 1 per cent. Walton's custom is to treat duodenal ulcers by posterior gastroenterostomy, whether or not they be causing tenosis and to reserve partial gastrectomy for the 4 per cent of cases that have developed a gastrojejunal ulcer. Nevertheless, he considers it feasible to determine the cases which are likely to develop gastrojejunal ulcer and to perform a primary gastrectomy on them. Increasing knowledge has contributed greatly to distinguishing these cases. As a rule they are probably cases in which the ulcer has begun early in life and cases showing an unusually high acidity.

HARMON TAYLOR, Walton's coworker, has also noted that the presence of hyperplastic gastritis as revealed by the gastroscope is a danger signal in such cases. In these cases Walton performs a partial gastrectomy. At the present time his preference is in the form of gastrectomy lies in the end-to-end gastroduodenostomy known as the Billroth I operation as it more closely follows the normal anastomosis and in his

experience seems to cause less operative disturbance but if the ulceration is extensive or the duodenum widely stenosed the Polya method is selected and gives good results. Walton believes that the modern tendency to divide the duodenum beyond the ulcer is unnecessary and adds to the risk. If the duodenal stump is securely closed, any area of active ulceration that may be left in the blind stump will always heal.

The surgical treatment of perforation may require more than simple suture to effect a permanent cure. Perforated ulcers are chronic lesions and recurrences sometimes take place. Walton states that in his own practice alone 63 cases were found which required an operation for an ulcer recurring or persisting after a previous simple suture for perforation. In England the accepted teaching is to do no more than a simple suture for perforation. In Russia and the Scandinavian countries the tendency is toward more radical steps, many of the cases being treated by immediate gastrectomy. Walton states that if one or two mattress sutures are used a firm closure can nearly always be brought about and reinforcement with omentum is unnecessary. He believes that there is a dangerous dogmatism today in denying the use of drainage. A suprapubic drain can never do any harm and while many cases do well without it Walton asserts that he has seen a number of examples of pelvic and subphrenic abscess which might have been prevented had drainage been instituted. A case of perforation that has recovered with simple suture must be carefully watched in a follow up department and not sent away as cured. There are so many recurrences that, in spite of all statements to the contrary Walton is convinced that a surgeon with wide experience is justified in early cases, in performing a gastroenterostomy at the first operation. His own figures have shown that the mortality is not increased thereby if a wise discrimination is made.

In the treatment of hemorrhage each surgeon must formulate his treatment upon the results of his own experience. The published mortality of cases treated medically varies from 4 to over 50 per cent. Walton treats all cases whether due to acute or chronic ulceration medically and operates only if both the physician and he himself believe that a second hemorrhage is probable and that if it occurs it will be fatal. Or if the hemorrhage has already recurred and the patient has survived a blood transfusion must always be given if an operation is undertaken being commenced immediately before the operation is started and continued as a drip transfusion after the operation. In theory undoubtedly the most satisfactory method of control would be the performance of a partial gastrectomy but the majority of surgeons believe that such an operation would generally be too severe a strain upon so ill and enfeebled a patient. The method of ligating arteries running to the ulcer which is often advocated has in Walton's experience generally been a failure for the arterial anastomosis is so free. Often the ulcers are

so large that any form of local excision is impracticable. In many cases of duodenal ulcer the anterior wall of the duodenum may be so widely invaginated by a running mattress suture that the lumen is entirely occluded and the anterior wall pressing firmly upon the ulcer safely controls the hemorrhage. The operation is completed by the performance of a posterior gastroenterostomy. In other patients, however the duodenal wall is so indurated that invagination is impossible. Under these conditions and with all large gastric ulcers the safest and most satisfactory method consists of opening the viscus underpinning the bleeding vessels and suturing the ulcer crater with interrupted mattress sutures. In the case of the duodenum the opening in the anterior wall should be embedded after suture and a posterior gastroenterostomy performed.

C. JENNINGS MARSHALL, the next speaker asserted that the primary treatment of duodenal ulcer is medical, the essential of which is physical and mental rest the one common factor of varied successful regimes and that in the treatment of severe bleeding symptoms disappear as rapidly with waterfasting as with any drug and diet system. It is vital however to distinguish between cure of the symptoms and cure of the ulcer as the ulcer persists long after disappearance of the x ray signs and occult blood in the feces. The hydrochloric figure by no means represents the peptic activity and is unreliable for estimation of progress and prognosis. While certain food abstentions relieve or minimize symptoms they cannot be relied on to secure freedom from recurrence nevertheless, only about one sixth of the cases need surgical intervention.

Perforation rarely heals without surgery and recurrent perforation calls for radical measures as does recurrent bleeding. Individual massive hemorrhages are primarily to be treated by functional rest and by leaving the blood pressure at the lowest level warrantable. Only after four or five days, when it is clear that arrest is not obtained, must surgery be considered. Massive transfusion then makes it possible to deal with a very difficult technical problem. Progressively frequent and more severe relapses leading to invalidism constitute the remaining surgical indication.

Undoubtedly a proportion, less than half of gastroenterostomies are very satisfactory. Gastrectomy is becoming less and less dangerous with adequate preparation oral hygiene, lavage, and attention to the hemoglobin and blood colloids breathing exercises and muscular and vascular tonus. Subjects with a good Bloots-McKesson ratio are suitable for spinal analgesia. bad risks need local and splanchnic blocking with cyclopropane or gas and oxygen. Prolonged anoxemia leads to serious postoperative myocardial danger. The stomach should be resected from high on the lesser curve to a little below the spleen. In deeply penetrating and extensive duodenal ulcer the stomach may be divided $\frac{1}{3}$ in proximal to the pylorus but it is essential to enucleate the antral mucosa. The possibility of leakage

General ill health, anemia, overfatigue and mental anxiety would lower resistance while heredity might determine a susceptibility. However these factors do not explain the primary cause. Diet, alcohol and tobacco do not seem to provide an explanation. The author states: Since the beginning of this century there have been wars, industrial stress and the strain of unemployment, and recently the added distress resulting from the bombing of so many of our cities and these may have had an influence. But the contrast of the incidence of ulcers in men with that in women during recent years can hardly be explained by such causes as it would seem women have been exposed to these conditions as much as men. The author adds that the high incidence of perforation and the quite serious mortality from acute hemorrhage seem to be a reflection on medical treatment and would seem to indicate more after-care. It is to be hoped that investigations the lines of those carried out by S. Wolf and H. S. Wolff (New York, 1931) may help to solve the difficulties of determining some primary cause of this really serious disease. M. THOMAS J. ST. JAMES

Walton, Sir J., Marshall, C. J., Evans, H. Tidy, Sir H. and Others: Discussion on Treatment of Duodenal Ulcer. *Proc R Soc Med Lond* 944 38 p.

This report gives the views of several well known members of the Royal Society of Medicine on the treatment of duodenal ulcer. Sometimes these views conflict, but the crux of the discussion is with regard to surgical treatment for duodenal ulcer revolves about the choice of procedure between gastroenterostomy and gastrectomy. It is brought out that a type of surgical treatment that is effective in the hands of one surgeon may be ineffective in the hands of another. Moreover the social environment of each patient has a direct bearing on the case. Likewise habitat or locale produces differences in the character of the ulcer.

Sir JAMES WALTON, president of the Section of Surgery, opened the discussion by warning the younger surgeons not to accept the written word without question but to find the truth for themselves. To counteract this danger Walton considers it essential for every surgeon to have a well organized follow up department in which he can conscientiously study his own results to prove his methods, if indicated. Immediately after the last World War Walton's hospital in London was equipped with what appears to be the first clinic of this sort in Great Britain. Walton's views are based on this twenty five year follow up study. Since technical surgery is an art, he states, no man is entitled to say that one form of treatment is alone correct. All that he can say is that it gives the best results in his own hands, others may find different methods more suitable.

It is generally conceded that the one indication for surgical interference is the failure of medical treatment. The presence of stenosis or hemorrhage

or even of perforation is in a sense evidence of this failure. Walton asserts that the standard of cure varies with the social position of the individual patient. Thus, a man in comfortable circumstances may keep free of symptoms and be apparently cured on a diet and in a sheltered life whereas the demands made upon a working man entail an entirely different set of conditions which would prove inadequate for cure in his instance.

The decision as to operative technique in England for uncomplicated cases lies principally between gastric resection and partial gastrectomy. In a few cases local excision with plastic procedures upon the pylorus may be the method adopted. The choice between partial or total gastroenterostomy and partial gastrectomy depends upon the frequency of gastrojejunal ulceration after posterior gastroenterostomy. Walton calls attention to the many reports that have been published by continental surgeons and some from the United States showing an incidence of from 1 to 15 per cent. These reports, he believes, have unduly influenced many English surgeons, but he is not in full agreement with conditions quite dissimilar to those in the countries whence the reports are issued and where partial gastrectomy seems to be the rule.

Walton states that in his carefully controlled follow up results the incidence has always been about 4 per cent and that these results have been constant. Moreover he states that while partial gastrectomy reduces the acidity to a greater degree it does not entirely remove the danger of this complication. In his own series of 16 gastrojejunal ulcers a partial gastrectomy had been previously performed in 12. There can be little doubt that of the two operations partial gastrectomy is the more severe. While many series have been published with a very low mortality it must be remembered that the operations were performed by surgeons exceptionally skilled in this technique. In the hands of the general practitioner this technique would probably show a death rate varying between 5 and 10 per cent, whereas with gastroenterostomy it should not be more than 1 per cent. Walton's custom is to treat duodenal ulcers by posterior gastroenterostomy whether or not they be causing stenosis and to reserve partial gastrectomy for the 4 per cent of cases that have developed a gastrojejunal ulcer. Nevertheless, he considers it feasible to determine the cases which are likely to develop gastrojejunal ulcer and to perform a primary gastrectomy on them. Increasing knowledge has contributed greatly in distinguishing these cases. As a rule they are probably cases in which the ulcer has begun early in life and cases showing an unusually high acidity.

HERMON TAYLOR, Walton's coworker, has shown that the presence of hyperplastic gastritis as revealed by the gastroscope is a danger signal in such cases. In these cases, Walton performs a partial gastrectomy. At the present time his preference is in the form of gastrectomy lies in the end-to-end gastroduodenostomy known as the Billroth I operation, as it more closely follows the normal anatomy and in his

experience seems to cause less operative disturbance but if the ulceration is extensive or the duodenum widely stenosed the Jolya method is selected and gives good results. Walton believes that the modern tendency to divide the duodenum beyond the ulcer is unnecessary and adds to the risk. If the duodenal stump is securely closed any area of active ulceration that may be left in the blind stump will always heal.

The surgical treatment of perforation may require more than simple suture to effect a permanent cure. Perforated ulcers are chronic lesions and recurrences sometimes take place. Walton states that in his own practice alone 62 cases were found which required an operation for an ulcer recurring or persisting after a previous simple suture for perforation. In England the accepted teaching is to do no more than a simple suture for perforation. In Russia and the Scandinavian countries the tendency is toward more radical steps many of the cases being treated by immediate gastrectomy. Walton states that if one or two mattress sutures are used a firm closure can nearly always be brought about and reinforcement with omentum is unnecessary. He believes that there is a dangerous dogmatism today in denying the use of drainage. A suprapubic drain can never do any harm and while many cases do well without it, Walton asserts that he has seen a number of examples of pelvic and subphrenic abscess which might have been prevented had drainage been instituted. A case of perforation that has recovered with simple suture must be carefully watched in a follow up department and not sent away as cured. There are so many recurrences that, in spite of all statements to the contrary Walton is convinced that a surgeon with wide experience is justified in early cases, in performing a gastroenterostomy at the first operation. His own figures have shown that the mortality is not increased thereby if a wise discrimination is made.

In the treatment of hemorrhage each surgeon must formulate his treatment upon the results of his own experience. The published mortality of cases treated medically varies from 4 to over 50 per cent. Walton treats all cases, whether due to acute or chronic ulceration medically and operates only if both the physician and he himself believe that a second hemorrhage is probable and that if it occurs it will be fatal. Or if the hemorrhage has already recurred and the patient has survived a blood transfusion must always be given if an operation is undertaken being commenced immediately before the operation is started and continued as a drip transfusion after the operation. In theory undoubtedly the most satisfactory method of control would be the performance of a partial gastrectomy but the majority of surgeons believe that such an operation would generally be too severe a strain upon so ill and enfeebled a patient. The method of ligating arteries running to the ulcer which is often advocated has in Walton's experience generally been a failure for the arterial anastomosis is so free. Often the ulcers are

so large that any form of local excision is impracticable. In many cases of duodenal ulcer the anterior wall of the duodenum may be so widely invaginated by a running mattress suture that the lumen is entirely occluded and the anterior wall pressing firmly upon the ulcer safely controls the hemorrhage. The operation is completed by the performance of a posterior gastroenterostomy. In other patients however the duodenal wall is so indurated that invagination is impossible. Under these conditions and with all large gastric ulcers the safest and most satisfactory method consists of opening the viscera underpinning the bleeding vessels and suturing the ulcer crater with interrupted mattress sutures. In the case of the duodenum the opening in the anterior wall should be embedded after suture and a posterior gastroenterostomy performed.

C. JENNINGS MANNING, the next speaker asserted that the primary treatment of duodenal ulcer is medical the essential of which is physical and mental rest the one common factor of varied successful regimes and that in the treatment of severe bleeding symptoms disappear as rapidly with waterfasting as with any drug and diet system. It is vital however to distinguish between cure of the symptoms and cure of the ulcer as the ulcer persists long after disappearance of the x ray signs and occult blood in the feces. The hydrochloric figure by no means represents the peptic activity and is unreliable for estimation of progress and prognosis. While certain food abstentions relieve or minimize symptoms they cannot be relied on to secure freedom from recurrence nevertheless only about one sixth of the cases need surgical intervention.

Perforation rarely heals without surgery and recurrent perforation calls for radical measures as does recurrent bleeding. Individual massive hemorrhages are primarily to be treated by functional rest and by leaving the blood pressure at the lowest level warrantable. Only after four or five days when it is clear that arrest is not obtained must surgery be considered. Massive transfusion then makes it possible to deal with a very difficult technical problem. Progressively frequent and more severe relapses leading to invalidism constitute the remaining surgical indication.

Undoubtedly a proportion, less than half of gastroenterostomies are very satisfactory. Gastrectomy is becoming less and less dangerous with adequate preparation oral hygiene, lavage, and attention to the hemoglobin and blood colloids, breathing exercises, and muscular and vascular tonus. Subjects with a good Moots-McCleson ratio are suitable for spinal analgesia. bad risks need local and splanchnic blocking with cyclopropane or gas and oxygen. Prolonged anoxemia leads to serious postoperative myocardial danger. The stomach should be resected from high on the lesser curve to a little below the spleen. In deeply penetrating and extensive duodenal ulcer the stomach may be divided $\frac{1}{4}$ in proximal to the pylorus but it is essential to enucleate the antral mucosa. The possibility of leakage

calls for precautionary drainage down to any dubious stump. Gastroduodenal anastomosis is permissible only when there is no gross stenosis or infection. The Polya Moynihan operation is frequently followed by "dumping" into the jejunum and duodenal reflux. The opening should be a little larger than gut caliber and the proximal jejunum should be hitched up to the gastric suture line an inch or so above the union.

HORACE EVANS approaches the subject of treatment of duodenal ulcer more generally from the medical angle. He asserts that while the diagnosis of duodenal ulcer is relatively easy in most patients and confirmation by means of x-ray satisfactory the history may in some instances be quite atypical, and conversely a typical history may be quite deceptive. This is true particularly he states, when the condition occurs in women. The frequency with which complications such as hemorrhages, perforation, and even stenosis occur in patients who have minimal symptoms of indigestion is surprising, although, no doubt, this is due in some of them to the fact that the ulcer is of a more acute type. This type of ulcer or superficial erosion may heal with little residual deformity and so reveal no x-ray change very soon after a hemorrhage.

Evans believes the treatment of duodenal ulcer to date remains eminently unsatisfactory. He considers the most satisfactory basic treatment to be essentially "medical," surgery being a useful aid in selected cases. He admits that surgery is essential in certain instances, as for example in perforation, pyloric obstruction, chronic perforating or adherent ulcers, and possibly in certain rare examples of hemorrhage in older patients. Likewise there are patients in whom adequate medical treatment has failed. In these cases gastroenterostomy and partial gastrectomy perhaps to an even greater extent, may yield excellent results. It is true, however that at medical clinics patients with postoperative ulcer who appear to have escaped surgical statistical surveys, lurk about in no small numbers.

Evans states that in the past five years he has been impressed by certain aspects of medical treatment. For instance he has found satisfactory healing to be unusual if the patient is ambulant. Complete bed rest for a minimal period of six weeks, followed by a further six weeks of quiet convalescence, is essential. In this disease the early disappearance of the pain, together with a host of economic and domestic difficulties, is an important factor in the generally unsatisfactory results. Mental relaxation is undoubtedly as important as physical. Evans regards phenobarbitone as of more importance than alkalis in this condition, the latter being demanded only when treatment is inadequate. He asserts that the frequency of food is probably of more importance than the nature of the food. In hospital practice the results of treating these patients in a special ward are striking. The necessary regime is universal and more easily and satisfactorily carried out. "the total exclusion of unsuitable foods, tobacco and

perhaps even the surgeon, makes the burden easier and recovery more rapid." The good psychological reaction under such conditions is worthy of note.

Evans states that in view of the unsatisfactory state of our present knowledge each patient must be managed according to his condition. Consideration should be given not only to the ulcer but to each patient's individual characteristics, economic factors, occupation and so on, all demanding particular attention. He believes that in all but the clearest cases it is good practice to co-operate with a surgeon from the outset, whether surgery is immediately in question or not. If the need for surgery arises, the importance of the state of the lungs, the presence of anemia, and possible dietetic deficiencies cannot be overemphasized. The risk of chest complications, so common after gastric operations, should be minimized by preoperative instruction in breathing exercises and the avoidance of the too tight abdominal binder rather than by the choice of anesthetic.

Sir HENRY TUDY, the next speaker called attention to the differences in the character of peptic ulcers observed in England and on the Continent, as well as to the differences between those seen in London and England and Scotland. He states that in London gastric ulcer is considerably more common than duodenal ulcer at the present time, while in Scotland duodenal ulcer is much more prevalent than gastric ulcer. Differences in the incidence of the two types of ulcer exist also in various social classes.

Tidy is of the opinion that our views on gastric pathology need revision, especially in view of the work of Wolf and Wolff (New York, 1943) who found that they could produce chronic gastric ulcer in four days and heal it in five days. The position is the same for gastritis. Gastroscopists now recognize the rapidity with which the gastric mucous membrane can change.

Tidy stresses the importance of discussion from time to time of the relative merits of medical and surgical treatment for peptic ulcers, since both are changing. Surgeons often appear to be satisfied that medical treatment has failed when the treatment followed would not have satisfied a physician. Frequently when a first course of medical treatment fails, a second course is successful.

Professor C. A. PANNETT agreed that undoubtedly a number of patients were cured of their duodenal ulcers by medical treatment, but he expressed surprise to hear an experienced surgeon state that uncomplicated intractable duodenal ulcer was a medical disease. He could see no reason why patients with this condition should not be transferred from wretchedly miserable complaining men to persons with a rosy outlook on life when all that was needed was a suitable operation, it being necessary to take away the affected part of the duodenum with a large piece of the stomach. Pannett states that the duodenum must be dissected free to a point beyond the ulcers so that a healthy duodenal wall is available for closure. He calls attention to the fact that many

years ago von Eiselsberg showed how frequently a gastrojejunal ulcer developed if the pylorus were left. Pannett declared he had given up the Billroth I anastomosis because the results following it were not so good as those following an operation of the anterior Polya type. He attributed this to the diminished mobility of the stomach which the former operation imposed.

The last speaker Taylor declared that he was not so much concerned with the treatment of acute complications, as with the situation which developed when a patient found himself having worse and worse pain and losing more and more time at his work in spite of all he could do in the way of conservative treatment. This type of patient calls for operative treatment, but the problem arises which operation to perform—partial gastrectomy or a gastroenterostomy. The former is without any question the more extensive and dangerous operation, but many surgeons have come to adopt it as a routine because of the incidence, about 25 per cent of anastomotic ulceration after gastroenterostomy. It is true that when gastroenterostomy is used indiscriminately the results are quite unpredictable; the operation in some cases being followed by complete and permanent relief of symptoms, but in others serving merely to aggravate them. What is needed is a means of preoperative segregation of the minority of potential failures of gastroenterostomy—partial gastrectomy being reserved for these, while gastroenterostomy is to be done in the majority of the cases. The speaker considered the test meal of some help, but too unreliable for this purpose. Taylor had employed a gastroscopic method with some success; he presented this method at the meeting. Eight years previous he had undertaken a gastroscopic study of the cases with persisting symptoms after gastroenterostomy in Sir James Walton's Follow Up Department at the London Hospital. The outstanding observation was that all these patients had a marked excess of gastric folds. Six control cases which had been cured by gastroenterostomy showed nothing like this degree of rugosity although the number of folds was more than in the average stomach.

These findings appeared to embody an explanation of the failure of gastroenterostomy in some cases and its success in others. It seemed that this operation would not be followed by stomal ulceration unless the gastric mucosa was grossly redundant, probably because of habitual hyperacidity. For the last six years Taylor has therefore gastroscopied all cases of duodenal ulcer before operation, and performed a partial gastrectomy on those with marked rugosity and a gastroenterostomy on the others. It was suggestive that the proportion of partial gastrectomies amounted to 25 per cent, just about the number of failures that would have been anticipated if all the cases had been subjected to gastroenterostomy.

The speaker considered it too early to draw final conclusions from these results, but he believed that they justified a return to the operation of gastroenterostomy except in those cases in which a gas-

troscopic estimation of the degree of rugosity in the stomach indicated the danger of recurrent ulceration. Only then was the more hazardous operation of partial gastrectomy justified.

MATTHIAS J. SKIFFERT, M.D.

Garlock, J. H. and Crohn, B. B.: An Appraisal of the Results of Surgery in the Treatment of Regional Ileitis. *J Am M Ass.*, 1945 127 305

The earliest experiences with the surgical treatment of ileitis seemed eminently satisfactory.

Experience in 164 instances of enteritis, terminal ileitis, and combined ileocolitis operations performed by many surgeons in many institutions is reported.

A primary resection of the disease process, usually of the pathological terminal ileum and the adjacent normal ileum and ascending colon was performed in 55 cases. Nine patients died postoperatively. Of the remaining 46, 9 developed recurrences in the ileum above the point of anastomosis, a recurrence rate of 19.5 per cent.

An ileotransverse colostomy or ileosigmoidostomy with transection of the ileum was carried out in 65 cases with no operative death but 9 recurrences of the disease must be recognized, a recurrence rate of 13.8 per cent.

A two-stage ileocolic resection which consisted of a primary short-circuiting ileocolostomy above the lesion with transection of the ileum followed after a period of time by resection of the original area of disease in the terminal ileum, cecum and ascending colon was done on 25 patients, with 3 postoperative deaths a mortality of 12 per cent. Eight instances of recurrent disease in the surviving 22 patients, a rate of 36.3 per cent, were noted.

No satisfactory medical treatment of ileitis exists. Chemotherapy has not been proved to be generally satisfactory in this disease.

Until the cause of the disease is discovered the treatment of ileitis remains surgical. The future improvement in the results of the operative treatment will rest on earlier diagnosis and more prompt operative intervention. With earlier diagnosis on the part of the physician and with greater experience on the part of the surgeon, especially as regards the choice of operative procedure, the future should hold promise of far better results.

Keynes, G: Rupture of the Pancreas. *Brit. J. Surg.* 1944, 3 300.

Two cases of rupture of the pancreas and its duct in young soldiers are presented. Both cases were uncomplicated at first, but one patient developed a persistent fistula, and both had serious complications during the postoperative course. Both of the patients recovered. The second case is of particular interest because it is probable that the rupture of the pancreas was due to under water blast, apparently the only example of this injury that has been described.

The first patient, aged twenty, was injured while riding a bicycle and colliding with a boom placed across a runway. He was struck in the epigastrium and shortly thereafter developed signs of acute abdominal crisis. Immediate operation revealed a rupture of the body of the pancreas over the vertebral column. No other viscus was injured. Drainage to the region of the injury was established. The fistula healed spontaneously but three months later it was found that a large pseudocyst had formed. This lesion was opened and drainage was re-established.

Roentgenographic study after lipiodol injection of the fistula indicated that the duct of Wirsung had been ruptured, since lipiodol entered the left two-thirds of the duct, but could not be seen to enter the right one third. Since spontaneous permanent healing of the fistula would not be likely without patency of the duct, it was decided to implant the fistula into the jejunum. This was done according to the procedure of Lehey and Llum. For several months after operation the patient experienced attacks of

abdominal disturbance, but he has been quite well for the past six months.

The second patient, aged twenty two was in a flying boat which crashed into the sea. He stated that he was uninjured in the crash and felt perfectly normal, having floated upright in the water supported by a Mae West belt. He was about 400 yards from a U boat which exploded as it sank from a depth bomb that had been dropped in its conning tower. At the moment of explosion he felt a peculiar sensation in the abdomen which he described as a "rumbling in the belly." He was rescued treated for shock, and operated upon about nineteen hours later. Operation revealed free blood in the peritoneal cavity and a tear in the peritoneum on the outer side of the hepatic flexure of the colon with retroperitoneal hemorrhage in this area. The retroperitoneal space was drained through a stab wound in the loin, the colon was sutured back in place, and the abdomen was closed. On the tenth day he developed a large swelling in the epigastrium, which was regarded as a pseudocyst of the pancreas, and the following day developed signs of acute intestinal obstruction. A second laparotomy was performed and the lesser peritoneal sac was opened through the gastrosplenic ligament. About 3 pints of muddy fluid were evacuated and examination of the pancreas through the opening revealed a vertical tear through the middle of the body. Ten days later he again developed signs of acute intestinal obstruction and a third laparotomy was performed. This revealed a volvulus of a loop of small intestine, which was reduced and the abdomen was closed. Drainage from the lesser peritoneal sac ceased about seventeen days after the second laparotomy. The patient had to undergo a fourth operation for repair of the large ventral incisional hernia. There were no further complications and he returned to full duty two months later.

GYNECOLOGY

UTERUS

Hafer J F: Conization and Early Diagnosis of Carcinoma of the Cervix. *Am J Surg* 1945 67 68

Carcinoma of the cervix is a common malignant lesion in the female. Its early diagnosis is absolutely essential for its successful treatment. The most certain way of making this diagnosis is by biopsy.

The author routinely does a radical conization of the cervix before subtotal hysterectomy for two reasons, (1) to sterilize the cervix, and (2) to obtain a biopsy. He has had no serious complications as a result of the conization. If the lesion on the cervix was suspected of malignancy, he always did a radical conization believing that if the cervix was not malignant, the removal of diseased tissue might have some prophylactic effect.

The conization is bloodless because of careful adjustment of the cutting and coagulation currents. A high current is used to achieve fast cutting with only a very thin layer of coagulation.

All patients for conization are admitted to the hospital. The most suitable time for conization is immediately after the menstrual period. When radical conization is done the patient receives sodium pentothal and oxygen and is hospitalized for three days postoperatively.

The patient is placed in the lithotomy position, the cervix and vagina are cleansed and the conization is carried out, the size of the loop being varied according to the size of the cervix and the amount of tissue that is to be removed. Before leaving the hospital the patient is instructed to avoid intercourse for four weeks, to take daily hot sitz baths, and not to be alarmed if menstrual bleeding occurs. On the fourth or fifth day the thin necrotic layer of tissue will slough and expose the granulation tissue underneath. This will have a slight tendency to bleed.

Only 2 patients in the entire series had to be hospitalized for bleeding. This occurred within one to two weeks after conization. The slough completely disappears in from three to six weeks and the cervix is smooth and has the appearance of almost a nulliparous cervix. Little or no scar tissue results from proper conization. Only moderate stricture formation was observed in 2 patients in the check up following radical conization.

Conization was done in 311 cases between July 1942 and October 1944. Among these 311 patients 18 malignancies and 11 squamous-cell metaplasias were found. All patients with metaplasia were urged to return for repeated check ups but comparatively few did so. Four cervical carcinomas were found accidentally in this series.

The author advocates conization for the prevention as well as for the diagnosis of malignancy of the cervix.

HENRY C. FALK, M.D.

Scheffey L. C. Farrell, D. M. and Hahn, G. A.: The Role of Injudicious Endocrine Therapy in the Delayed Diagnosis of Uterine Cancer. *J Am Med Ass* 1945 127 76.

The authors call attention to a practice that is proving to be a serious factor in the delayed diagnosis of uterine cancer namely the indiscriminate use of endocrine therapy for the control of abnormal bleeding from the genital tract, when an organic cause for such hemorrhage has been either undiscovered or ignored. Delay in diagnosis is the most important explanation of the low curability rate of uterine cancer.

Granted that cancer of the uterus may exist in a very small minority of patients without causing any untoward symptoms whatever clinical experience and statistics prove that in the vast majority of instances abnormal bleeding from the genital tract is the most frequent symptom of the disease.

Cervical cancer may occur at any time during the reproductive period although the majority of patients afflicted are in the menopausal or postmenopausal period. Twenty-seven per cent of the patients observed in the Department of Gynecology of the Jefferson Medical College Hospital, Philadelphia, have been women under forty years of age when first seen.

Biopsy must be depended on for certainty of diagnosis. Fundal cancer is usually manifested primarily by postmenopausal bleeding. This has been true in 79 per cent of such patients seen at this hospital. The remaining 21 per cent were over forty years of age however and had not yet ceased menstruating when the diagnosis was made.

Curettage is essential to establish an accurate diagnosis and to determine proper treatment.

When abnormal bleeding is present during the late reproductive, menopausal, or postmenopausal periods there is much less justification for prolonged and experimental endocrine therapy. Well recognized radiological and surgical measures are available in such cases, not only for the relief of organic pelvic disease, but even for the correction of proved functional bleeding—measures that are surer and far less time-consuming than prolonged and often ineffective endocrine therapy.

HARRY W. FRANK, M.D.

EXTERNAL GENITALIA

Compton B. C. Bieren, R. E., Jones, E. G. Inoles B. II., Jr and Others: The Treatment of Gonococcal Vulvovaginitis. *J Am. Med Ass* 1945 127 6.

The authors studied 442 cases of vaginal discharges in children 318 (72 per cent) showed gonococci on direct smear.

In this study a careful history was taken and included duration of the illness, the number of chil-

dren in the home, the individuals with whom the child slept and played and the school which the child attended.

A complete physical examination was made, including examination of the breasts for tenderness, secretion, and size. The amount of vaginal discharge or bleeding was noted. A smear was taken by inserting an applicator high in the vagina on each visit.

On making the diagnosis the mother was told the importance of relative isolation of the child and instructed in the use of the commode, towels, and clothing.

The child was examined at weekly intervals until three successive smears were negative. She was then seen at monthly intervals until the smears had been negative for three months. She was then seen at three-month intervals, and discharged when well for one year.

The child was allowed to return to school as soon as the symptoms entirely cleared and the smear became negative.

Of the 318 cases of gonococcal vulvovaginitis which were diagnosed and treated, 153 were successfully followed up for one year after the smear became negative. Of the 153 cases, 122 were treated with oral or vaginal-suppository estrogens (natural or synthetic), 12 with sulfathiazole or sulfadiazine, 10 with a combination of estrogens and sulfonamide drugs, 6 with Floraqin suppositories or insufflation, and 1 with Floraqin and estrogen.

Of the 122 patients treated with estrogens, 33 had a recurrence. Of the 12 treated with sulfonamide drugs, 2 had a recurrence.

In the sulfonamide cases the discharge diminished in two or three days. The smears became negative by the end of the second week. No patient was treated with a sulfonamide drug longer than three weeks. No untoward reactions were noted. The dosage of sulfathiazole which was given orally was 0.5 gm. per day to children from six months to one year, 1 gm. per day to children from one year to four years, and from 1.5 to 2 gm. per day to children between five and ten years. Sulfadiazine was given orally in half the dose for sulfathiazole.

The estrogens were used either as suppositories (natural or synthetic) or in oral medication (synthetic). The dosage of diethylstilbestrol was 0.5 mgm. per day for children between six months and one year, and from 1 to 3 mgm. per day between one year and ten years.

The average total dose of natural estrogens until complete cornification and a negative smear occurred was approximately 35,000 international units.

The most common untoward reaction was an effect on the secondary sex characteristics, slight hypertrophy of the breasts, clitoris, and labia. A few children developed nausea, slight vaginal bleeding, or the growth of pubic hair. All of these changes

receded as soon as the drug was stopped; no permanent change was noted.

In the estrogen treated cases the discharge disappeared in about two weeks. Gonococcal peristasis a week or two longer in the stained smear while the patient is continued on estrogens. If a child is followed until the smear becomes negative the danger of infection and the danger of recurrence of the highly infected discharge has passed. By the end of one year the disease has usually been cured spontaneously. If not by the action of the drug used.

MISCELLANEOUS

Leatham, J. H., and Abarbanel, A. R.: Gonadotropins and the Antihormone Problem. *West. J. Surg.* 94:4, 5, 491.

The authors note that the combination of extract from the anterior pituitary lobe of the sheep and human chorionic gonadotropin (synapoidin) has received little consideration with regard to its antigenic activity. Investigators have reported a negative test for antigens to this hormone combination in 1 patient. Other investigators have noted allergic manifestations following hormone administration. It is generally agreed that chorionic gonadotropin is not antigenic in the human being. From reports given, one can assume that the chorionic gonadotropin in synapoidin is not antigenic. However, the material also contains extract of the anterior pituitary lobe of the sheep which potentially could be antigenic. There are very few reports in which anterior pituitary lobe extracts have been administered clinically and in which tests for antigonadotropins have been made.

It seemed desirable to the authors to investigate further the question of antigonadotropins in patients treated with synapoidin. The results of 3 cases are presented and herewith reported. The methods used in these studies are described. The serum of each patient was tested for antigonadotropins against synapoidin before the hormone treatment was begun and no antagonistic substance to this combination of gonadotropins was detected. During the course of therapy with synapoidin, sera tests were performed at various intervals from the time of the first injection. A detailed tabulation of the test data obtained from 2 of the patients is shown.

Antigonadotropic substances were not detected in the sera from 3 patients injected with a combination of extract of the anterior pituitary lobe of the sheep and human chorionic gonadotropin. The maximum period of hormone administration was five months. No allergic manifestations were noted and skin tests were negative. The sera of 6 amenorrheic women were tested for antagonists to synapoidin prior to therapy. All tests were negative.

HENRIET F. THURSTON, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Sesley W F: A Study of 250 Cases of Placenta Previa. *Am. J. Obst.* 1945 49 85

For a ten-year period from 1933 to 1942, there were 31,956 deliveries at the Harper and Herman Kiefer Hospitals, Detroit Michigan among which there were 250 cases of placenta previa, 1 in 128. Placenta previa is found in primiparas and multiparas in the ratio of 1 to 5. It is more common in white persons than in colored. It occurs most commonly in the middle childbearing age.

A high percentage of twin pregnancies and fetal malformations is to be expected among cases of placenta previa.

A large group of such cases was satisfactorily managed by expectant treatment during the stage of dilatation or by simple rupture of the membranes.

The insertion of the dilatable bag gives good results in cases adapted to its use.

In properly selected cases cesarean section can be used to the advantage of both mother and child.

Seventy five per cent of the cases in which roentgenography was used were correctly diagnosed by this means.

Blood transfusion should be available to all patients with placenta previa. An acceptable mortality rate cannot be expected without it.

The maternal mortality in 250 cases of placenta previa taken from a large metropolitan area was 2.3 per cent. The gross fetal mortality was 34.6 per cent the net, 14.4 per cent.

EDWARD L. CORNELL, M.D.

Allen, E. D.: Pregnancy and Otosclerosis. *Am. J. Obst.*, 1945 49 32

Attempts to collect data have convinced the author that difficulties in hearing during pregnancy are frequently overlooked, neglected entirely and often inadequately studied. A very careful family history concerning deafness should be taken of every pregnant woman who experiences appreciable changes in hearing.

For progressive deafness to be considered an indication for therapeutic abortion, a definite diagnosis of otosclerosis must first be made.

Definite otological evidence should be obtained and preserved before, during and following pregnancy and lactation for evaluation concerning succeeding pregnancies.

Otosclerosis should probably not contraindicate marriage or a trial pregnancy.

Otosclerosis should not be considered as an indication for therapeutic abortion in the primipara.

Deafness need not be present, but a familial history of deafness may be one of the deciding factors for the interruption of pregnancy. A multiparous woman may have considerable right to question

the continuation of her pregnancy if accurate otological evidence obtained in previous pregnancies has shown a marked *sustained* loss of hearing.

Before therapeutic abortion is decided upon the patient should be informed that otosclerosis is a progressive disease even without pregnancy also that hearing aids and lip reading offer great help.

Fetuses in all stages of development born to mothers with decreased hearing should be preserved for examination by a competent otological pathologist. This applies especially to twins.

EDWARD L. CORNELL, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Dingle, P.: Prophylactic Use of Pneumoperitoneum in the Puerperium of Tuberculous Patients. *J. Obst. Gyn. Brit. Empire* 1944, 51 499.

The present accepted treatment of tuberculous patients who become pregnant has been to induce an abortion up to a period of four months. More advanced pregnancies are permitted to proceed to term because the results of late abortion are as serious as those of pregnancy at term. During the past two years it has been possible for the author of this report to study a series of 30 consecutive cases of patients suffering from pulmonary tuberculosis. These patients were not seen in either the tuberculosis clinic or the antenatal clinic until after they were well into the fifth month of pregnancy.

The treatment of these patients consisted of

1 A sufficiency of rest, food, and fresh air during the antenatal period. pneumothorax was used when indicated.

2 The first stage of labor was made as comfortable and as easy as possible by the administration of suitable drugs. the second stage was shortened and the strain reduced by an episiotomy or by the use of forceps.

3 In the puerperium, a pneumoperitoneum was induced within one hour of delivery by the inflation of 3,000 cc. of air or air-oxygen mixture into the peritoneal cavity. one week later 2,000 cc. were given, and after a period of one more week, 1,000 cc. were given. The mother was put on complete bed rest and did not feed her infant by breast except in 1 or 2 instances.

Thirty cases were studied. In the first group there were 4 with a positive sputum and bilateral active disease. 2 had a hopeless prognosis, and of these, one died and the other was seriously ill. the remaining 2 were greatly improved at the end of six months. In group 2 also consisting of 4 patients having a positive sputum with unilateral disease. 1 was unco-operative and died. the 3 others are making satisfactory progress. Group 3 comprised 2 patients with active disease, as was shown by x rays but with negative sputum and both showed im

provement after a period of six months. Group 4 totaled 8 patients with unilateral disease, all of whom were progressing satisfactorily after a period of six months. Group 5 consisted of 3 patients who had a thoracoplasty seven and ten years respectively prior to delivery and the condition of both remained satisfactory. Group 6 comprised 3 patients with pleurisy only both patients were benefited. Group 7 comprised 3 patients with a phrenic crush, or an avulsion 1 progressed satisfactorily and 1 was too recently delivered to permit an evaluation. Group 8 comprised 6 patients with quiescent, or healed disease all were benefited.

The final observation in this study was that of the 30 patients, 25 passed through labor and the puerperium and are doing well 5 more are in the early puerperium. The author concludes that the use of pneumoperitoneum is advocated as a prophylactic measure in the treatment of tuberculous patients in the puerperium.

MISCELLANEOUS

Jones, G. E. S., Delfs, E., and Struss, H. M.: Chorionic Gonadotropin and Pregnanadiol Values in Normal Pregnancy. *Bull. Johns H. Mem Hosp.* 1944 75 359.

The authors have studied the chorionic gonadotropin serum levels and urinary pregnandiol values of 18 women throughout normal pregnancy. In an additional 6 women the chorionic gonadotropin levels only were studied. Two cases of twin pregnancy were also observed for chorionic gonadotropin only 1 of them being observed for pregnandiol.

The findings revealed that the curve for serum chorionic gonadotropin rises precipitously reaching a peak between fifty and sixty-five days from the first day of the last menstrual period. The level then declines gradually until about the 100th day then a still more gradual decline for the next thirty days, and finally the level is maintained low until the end of pregnancy. There is a slight hint of a secondary rise between the 100th and 130th days, but this is probably unimportant.

The actual levels in this study started at about 3,000 I.U. per liter and rose to a peak of 150,000 I.U. per liter gradually declining to between 10,000 and 15,000 I.U. and finally to between 1,000 and 6,000 I.U.

The amount of free pregnandiol in the urine of pregnant women was calculated in milligrams per twenty-four hours. The pregnandiol excretion curve can be divided into 3 periods: that in which the corpus luteum is the main source of progesterone production and that in which the placenta is probably

the most important site of progesterone formation. During the first period which ends between the sixty-fourth and seventy-eighth days, the pregnandiol values are rarely above 30 mgm. or below 6 mgm. per twenty-four hours. Throughout the remainder of the pregnancy there is a gradual rise in the pregnandiol-excretion curve until about the 350th day when the peak values are attained. The average peak value was 85 mgm. per twenty-four hours.

Two cases of multiple pregnancy were observed. One showed abnormally high chorionic gonadotropin values maintained throughout pregnancy while the other showed only moderately high values in the first half of gestation and a normal curve in the second half of pregnancy.

The pregnandiol studies in the one case of twins in which they were observed revealed figures compatible with those found in the women with single pregnancies.

There was a rather wide individual variation in the cases studied, but a very definite average was demonstrable.

HARRY FINE, M.D.

Halbrecht, L.: Artificial Insemination (Report on 80 Cases). *J. Obst. Gyn. Brit. Empire*, 1944, 51: 556.

The indications for the adoption of artificial insemination were divided into three groups:

1. Defective spermatozoa
 - a. Severe oligospermia
 - b. Necrospemia
 - c. Faulty germ plasma
 - d. Azoospermia
2. Anomalies of the male external genital organ
3. Sterility without evidence of its cause in either of the partners

Azoospermia and severe oligospermia were considered as absolute causes of sterility.

The intrauterine and intracervical techniques were used. The former was abandoned because of technical difficulties and unnecessary risks, except when stenosis and atresia of the cervix were present.

Two unsuccessful attempts at insemination were made with refrigerated spermatozoa and 3 others with aspirated testicular material from husbands suffering from obstruction of the genital passages due to gonorrhea.

Three or four inseminations were made between the twelfth and eighteenth days for from 3 to 6 cycles. The donors were selected with the usual precautions.

In 23 of 53 cases of sterility associated with defective sperm pregnancy occurred. Of 18 patients to whom the husband's semen was used, 3 became pregnant.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Warren F. L.: Estimation of Urinary 17 Ketosteroids (a) Adrenal cortical tumors in the male and female (b) pituitary basophilism adrenal virilism or hirsutism in the female without tumor (c) pubertal virilism in female children without tumor and (d) miscellaneous conditions such as carcinoma of the breast, seminoma of the testis, and so on. Data are given for 92 patients studied by the author as well as for 20 cases of adrenocortical tumor reported previously by others.

The author presents an extensive review of the levels of the urinary 17 ketosteroids in the following conditions: (a) adrenal cortical tumors in the male and female (b) pituitary basophilism adrenal virilism or hirsutism in the female without tumor (c) pubertal virilism in female children without tumor and (d) miscellaneous conditions such as carcinoma of the breast, seminoma of the testis, and so on. Data are given for 92 patients studied by the author as well as for 20 cases of adrenocortical tumor reported previously by others.

The values found in the 4 cases of adrenocortical carcinoma studied by the author ranged from 83 to 690 mgm per day. The majority of values found by other workers were in this range. For the group of individuals all female, classed as cases of pituitary basophilism adrenal virilism or hirsutism without adrenal tumor, the range of values reported by the author was from 3.4 to 37 mgm per twenty four hours, with a mean value for the three groups of 18.6, 22 and 16 mgm. These values are in nice agreement with those reported by Crooke and Callow and others for similar patients. Cases of pubertal virilism in female children showed a range of from 8.4 to 100 mgm. per day. Again these values of the author were in agreement with the findings of other investigators.

In addition to analytical data problems arising in the clinical differential diagnosis of the aforementioned conditions are discussed and evidence is added to that of Crooke and Callow as well as of others that the differentiation of adrenocortical tumor may be made by estimating the greatly increased excretion of urinary 17 ketosteroid particularly the beta fraction. Excretion in cases of proved tumor are usually well above the range for conditions such as pituitary basophilism but an intermediate zone exists in which interpretation is difficult. However in the cases cited in which separations are reported, dehydroisoandrosterone in large amounts was found only in patients with adrenocortical carcinoma. In 2 cases of pubertal virilism in children with values for total 17 ketosteroid between 90 and 140 mgm, large amounts of androsterone were isolated. Dehydroisoandrosterone was either absent or present in an amount too small to be isolated.

DONALD F. McDONALD M.D.

Dodge, H. J. and Benner M. C.: Neuroblastoma of the Adrenal Medulla in Siblings. *Rocky Mountain M. J.*, 1945 43 35

Although sufficient cases of tumors of the sympathetic nervous system particularly neuroblastoma

mas, are now on record so that distribution as to age, sex, race and primary site of development is well established there are only two references to a familial incidence of these tumors in the English literature and no proved cases on record.

The authors present case histories and pathological data of 2 siblings, one a four year-old female and the other a seven month-old male who died with neuroblastomas of the right adrenal gland. The presenting complaint was abdominal enlargement in both cases. In the older child a mass appeared two months following the initial abdominal enlargement, whereas in the infant a very large mass was found on first examination. The clinical course of the disease was short.

Only a few weeks in the infant and three months in the four year-old child. Pathological examination revealed only local extension of the tumor in the older child but there were extensive hepatic metastases in the infant. A third child of this marriage, now one year old is apparently free of the disease.

The infrequency of familial neuroblastomas derived from the sympathetic system is reflected in the lack of recorded proved cases in the literature. It is believed that this is the first adequately proved instance of familial neuroblastoma.

DONALD F. McDONALD M.D.

Smith E. C. and Orkin L. A.: A Clinical and Statistical Study of 471 Congenital Anomalies of the Kidney and Ureter. *J. Urol. Balt.* 1945 53 1

Malformations of the kidneys and ureters are of great clinical importance and account for about 40 per cent of all pathological conditions akin to these organs. They can be diagnosed by complete urological investigation especially excretory urography.

In a large series of 18,460 consecutive urological admissions, the authors found 471 instances of congenital anomaly. The incidence according to this data would be 1 to 40 but this is much too low. Since the introduction of excretory urography in the authors' hospital the incidence has been found to be 1 to 27 (3.7 per cent).

While the most frequent congenital anomaly is that of double renal pelvis and ureter which occurred 97 times, or a clinical incidence of 1 to 190 the other anomalies occur frequently enough to warrant attention.

A consideration of the individuals in this series shows that the average age was thirty-seven years that males were slightly more affected than females the ratio being 250 to 221, and that there was no apparent predilection for either the right or left side. Considered together unilateral involvement is at least four times more frequent than bilateral involvement.

Although anomalies are compatible with a healthy existence this is the exception rather than the rule.

as this occurred in only 17 per cent of the cases. Practically any urological symptom may be encountered but the most frequent is that of pain which occurred in 78.9 per cent of the cases. A further study of symptomatology reveals that the anomalous kidney may produce symptoms without the presence of associated renal disease.

In the series of anomalies, only 20.5 per cent showed no associated pathological changes to illustrate the point that the malformed kidney is especially prone to disease. Considered together urinary infection, hydronephrosis, and calculus accounted for 89 per cent of the secondary pathological findings in these cases.

In this study 138 cases (30.3 per cent) required open surgical intervention for the relief of this condition, which was almost equally divided between the operation of nephrectomy and conservative procedures.

Since congenital anomalies have been shown in this article to be especially prone to disease, it is believed that only by early diagnosis and treatment can a good many of these complications be prevented or ameliorated. And with the use of chemotherapeutic agents, the ease and ability to perform conservative and plastic procedures will certainly increase in the instances of congenital anomalies that come to open operation.

JOSEF A. LOSEY, M.D.

Cooley T. F. and Walker J. H.: Congenital Solitary Kidney: Case Reports and Consideration of Military Significance. *J. Urol.*, Balt., 945 534

The recognition of congenital solitary kidney during life has been made possible by the use of pyelography. The incidence of the anomaly must be in the neighborhood of 1 in 1,000 as judged from autopsy reports. Criteria for diagnosis are (1) absence of the renal silhouette on the abdominal flat film (2) roentgenological evidence of renal enlargement and (3) possible asymmetry of the psoas shadows, (4) absence of opaque media on the agraphic side on the ureteral excretory urography (5) absence of the ureteral orifice on one side after repeated cystoscopic examination in an otherwise normal appearing bladder and (5) absence of indigo-carmin elimination on the affected side. A sixth corroborative criterion is an associated abnormality of the genital tract, which is far more common in the female because of the later development of the müllerian system.

The authors present a case of sulfadiazine crystalluria and oliguria in a twenty-six year-old male who had received 84 gm of sulfadiazine in eighteen days as treatment for gonorrheal urethritis. Investigation of the upper urinary tract revealed a congenital solitary left kidney. A second case, that of a twenty-nine-year-old male complaining of frequency, urgency, and nocturia of ten years' duration, is reported. He also complained of right sacroiliac pain of three years duration. Physical and urological findings of significance were lumbar scoliosis, bilateral pes planus, left varicocele, and a well

marked prostatitis. Laboratory findings were normal. Urinalyses were normal and excretory pyelograms and cystoscopy showed a congenital solitary left kidney.

The authors conclude that the anomaly is generally silent and clinical recognition most frequently results from an incidental investigation. The relative frequency of occurrence and the finality of the error if a single kidney be removed makes it essential that pyelography be performed prior to any surgical procedure upon the upper urinary tract. The incidental discovery of the anomaly when the solitary kidney is normal is neither an indication for resection nor an adequate cause for discharge of a patient from military service.

DONALD F. McDONALD, M.D.

Frien E. L. The Mechanism of Renal Complications in Sulfonamide Therapy. *N. England J. M.* 945 23 63

Renal complications to sulfonamide therapy continue to occur despite an increasing experience and the use of the more soluble sulfonamide drugs. The usual mechanism that produces these complications is the obstruction of the urinary channels by insoluble concretions composed principally of the acetyl derivatives of the drugs. Less frequently a toxic injury of the tubules, independent of concretions, produces anuria and uremia. In such cases the only lesion in the urinary tract may be a widely disseminated focal necrosis affecting the kidney tubules.

Two cases of sulfathiazole anuria and uremia are reported. No obstructing concretions were encountered in the ureters or kidney pelvis by cystoscopy and pyelography. Renal decapsulation was done and cortical biopsies were taken. One patient died, and the other recovered rapidly, apparently as a result of decapsulation. There were no crystals or concretions in the kidney tissue taken by biopsy nor in the entire urinary tract (including the kidney tubules) of the fatal case that came to autopsy. A rigorous technique that precludes the loss of drug crystals in preparation of the tissues is described.

The most important factor in the causation of renal complications is a low urinary output.

The development of obstruction concretions depends on two physical conditions—the hydrodynamics of the urinary tract and the affinity of crystals for each other.

Crystals of the sulfonamides first form in the convoluted tubules, where reabsorption of water occurs. Sedimentation of these suspended crystals occurs in the terminal portions of the collecting tubules and in the renal calyx. Proximity of the crystals here results in aggregation and the formation of concretions that obstruct the terminal portions of the collecting tubules. This process progresses in a retrograde manner upward in the collecting tubules. Calyces concretions remain in situ or pass down the ureter much as do ordinary urinary calculi.

DONALD F. McDONALD, M.D.

It has been only in the past twenty years that the realization of the fact that gastrointestinal symptoms may predominate in cases of malignancy of the kidney has been reflected in the literature. That these symptoms are related to the common innervation of the gastrointestinal tract, the kidney and the ureter has been attested by anatomists, clinicians, and researchers.

In order to assess the possible value of the type of gastrointestinal symptoms the frequency of occurrence, and the possible relationship to the histological type of the renal tumor a study of all proved renal tumors at the Beth Israel Hospital New York, was made. In five years 33 cases of which 22 occurred in men and 11 in women were found. There were 22 hypernephromas (65 per cent) of which 10 were presented with only gastrointestinal symptoms. In the remaining 11 cases the patients complained of hematuria. Tumors of the renal pelvis occurred in 6 cases, or 17 per cent, and all of these presented only urological symptoms, usually painless hematuria. There were 3 cases of renal carcinoma in none of which was there ever any positive urinary symptoms or findings. These 3 cases were explored with the possibility of ovarian or gastrointestinal neoplasms in mind. There was 1 case of lipoma of the kidney and 1 case of retroperitoneal tumor of undetermined histopathology in which gastrointestinal symptoms predominated.

There was found to be no differential value to the type of gastrointestinal symptom associated with renal tumors which would distinguish between gastrointestinal and renal disease. In all 3 cases of renal carcinoma there was no urologic complaint. In all cases of tumor of the renal pelvis there were urologic symptoms without any gastrointestinal symptoms. Twenty three of the series or 69 per cent, had gastrointestinal symptoms and a fair number showed no urologic findings.

It is suggested that any cases presenting disturbing abdominal symptoms with negative findings should have a complete urologic investigation.

DONALD F. McDONALD, M.D.

Abeshouse, B. S. and Weinberg, T.: Malignant Renal Neoplasms; A Clinical and Pathological Study. *Arch. Surg.* 1945 50 46.

A study of 63 renal neoplasms observed during the past twenty years, and a review of the literature warrant the following conclusions.

Renal neoplasms are more common in men than in women. They occur with equal frequency in each kidney. Parenchymal renal neoplasms occur most frequently in the sixth and seventh decades of life, with the exception of the Wilms tumor which occurs in early infancy and childhood.

The most common initial symptom is painless hematuria. Next in frequency are pain and a tumor mass. The classic symptom triad which may be ob-

served during the course of the disease is found in the following order of frequency: pain 94 per cent, hematuria, 81 per cent, and tumor mass, 63 per cent. This symptom triad is usually reversed in children with Wilms tumor and in inoperable adults in whom a mass is usually the most prominent symptom.

Retrograde pyelographic studies were performed in 56 cases, and a correct preoperative diagnosis, based on the pyelographic findings was made in 42 cases. Greater reliance should be placed on retrograde pyelography than on intravenous urography in the diagnosis of renal neoplasms. The most common urographic findings in order of frequency are compression of one or more calyces, elongation of one or more calyces, distortion or compression of the pelvis, displacement of the ureter or the pelvis dilatation of the pelvis, and calcification within the tumor. In parenchymal neoplasms, the characteristic change is compression, elongation, or obliteration of one or more calyces. In pelvic tumors a filling defect of the pelvis is the most common finding.

Among 53 cases treated by nephrectomy there were 4 deaths. Surgical intervention is justifiable in every case of suspected renal neoplasm. Early diagnosis and operation increase the chance of cure.

The prognosis is influenced by the nature and duration of the symptoms, the condition of the patient, the type, size, and mobility of the tumor, the presence of tumor thrombi in the renal vein and in the inferior vena cava, the presence of metastases, the type of surgical treatment, and irradiation therapy.

The best results following nephrectomy from the standpoint of survival were obtained with Grawitz tumors. The poorest results followed operation for pelvic neoplasms.

SAMUEL KAHN, M.D.

Percival, R. C.: Ureteral Calculus Treated by Reversed Catheterization. *Lancet*, Lond., 1945 248 15.

The ureteral calculus, recently impacted and showing no sign of progress under observation, is not rare. Several procedures for dealing with such calculi have previously been described but no one method is sufficiently reliable to merit use routinely.

A simple and effective method of extracting a small recently impacted calculus is described. The principle of the method is gradual ureteral dilatation through intermittent traction on a ureteral catheter made to form a loop which grips the stone. In 50 cases reported by Finney and in the 3 cases reported by the author no complications of any kind were encountered.

SAMUEL KAHN, M.D.

Vest, S. A.: Conservative Surgery in Certain Benign Tumors of the Ureter. *J Urol* Balt., 1945 53 97.

Treatment of all types of ureteral tumor whether benign or malignant, has usually consisted of removal of the kidney and ureter. So far as the writer is aware, not one author has indicated in his report any evidence of metastases following treatment of benign ureteral tumors. Many authors have been questioned

Fig. 1. Showing villous and sessile papilloma composed mainly of epithelial tissue. The cells are well differentiated and tend to become polygonal and flat near the surface. There were no mitoses and absolutely no invasion of the basal membrane. This characteristic appearance was confirmed throughout the other sections.

but no reports of recurrences have been received. The author believes from the study of previously reported cases in the literature and his own experience that benign and nonmetastasizing tumors do occur and, when favorably situated and properly diagnosed, can be treated conservatively. Three cases are reported and the writer believes from a standpoint of the previous history, the clinical and pathological findings, and the course since operation, that the lesions can be considered as benign tumors.

Case 1 was that of a sixty-three-year-old male with a history of symptomless hematuria of one week's duration. Four months previously he had had renal colic on the right side without calculi or hematuria. Cystoscopy of the bladder was essentially normal with the exception of a small papillary tumor about 1 by $1\frac{1}{4}$ cm. in size which obscured the right ureteral orifice. A ureteral catheter was passed to the left kidney with ease on the right side it went through the middle of the tumor to the kidney. X-ray showed a normal kidney and ureter on the left, but on the right side there was considerable dilatation of the ureter and kidney pelvis with an irregular filling defect in the lower ureter. Biopsy showed the tumor to be benign and papillary in character. The pyelogram indicated no evidence of tumor elsewhere in this ureter or the kidney pelvis. At operation when the ureter was opened a large papilloma extruded the tumor was readily lifted out of the ureter and found to have a base with a diameter of from 1 to $1\frac{1}{4}$ cm. It came off abruptly from the normal mucosa with no puckering induration and no evidence of invasion. The ureteral wall was soft and pliable and there was not the slightest suggestion of malignancy. The tumor was excised with a wide margin of ureteral wall around the base following which the ureter was sutured with continuous fine

catgut. The pathological study (Fig. 1) revealed a papillary tumor with uniform cells and no mitoses or invasion of the basement membrane. For the past seven and one half years the patient has returned for periodic observation. He has had no urinary symptoms and no hematuria. Pyelograms have shown no evidence of recurrence.

Case 2 was that of a fifty-two-year-old male with a history of painless hematuria of eight days duration. Cystoscopy showed a normal bladder and ureteral orifices, both of which ejected urine in the usual manner. The urine from the left was bloody. A catheter was passed to the right kidney with ease but on the left side the catheter would not pass the region of the midureter. Plain x-rays were normal. The pyelogram was normal on the right side, while on the left the lower ureter showed a beginning dilatation just above the brim of the pelvis. Opaque media filled the spindle-shaped dilatation up to a certain point at which it abruptly stopped. Intravenous x-rays showed a normal ureter on the left side except for a spindle-shaped dilatation of the midureter. When the ureter was exposed at operation there were no extrureteral masses, adhesions, obstructions, or induration. The ureter was opened longitudinally over the dilated portion and a black spindle-shaped mass about $1\frac{1}{4}$ cm. in diameter and 4 cm. long was removed. It was bulbous below and running out into a fine filamentous termination above. Frozen section of the ureteral wall showed only hypertrophy of all layers. Frozen section of the mass disclosed a papillary necrotic tumor which seemed to be benign. The tumor was lying loose in the ureter and above this section a small area of thickening in the ureteral wall could be felt. This was the previous point of attachment of the papilloma and was removed together with a margin of the surrounding normal wall of the ureter. A frozen section of this base of the new growth revealed an apparently benign papilloma (Fig. 2) only the mucosa was involved with no evidence of infiltration. No other evidence of any more papillomas could be found or felt in the pelvis of the kidney or the remainder of the ureter. The ureter was, therefore, closed over a small catheter by an end-to-end anastomosis with four sutures of No. 0000 chromic catgut. This patient has been followed from time to time with both intravenous and retrograde pyelograms, all of which have been entirely normal; there has been no hematuria or urinary symptoms and the urine on repeated examination has never shown red blood cells.

Case 3 was that of a fifty-nine-year-old Army medical officer who had undergone frequent fulgurations since 1908 for hematuria and a papillary tumor emerging from the right ureteral orifice. In 1937 the pyelogram showed normal kidneys with a dilated right lower ureter and a filling defect. At this time the tumor was fulgurated with the aid of a small meatotomy. At the operation in 1943 the ureter was found to be dilated from about the brim of the pelvis down to the bladder. It was opened with a longitudinal incision and a single papillary tumor was

Fig. 2. Pathological study a, Left Section of urethral wall including tiny base or origin of pedunculated tumor. Urethral wall is entirely normal in appearance. Base of the papilloma is composed of small, thin, spindle-shaped cells with absolutely no evidence of invasion. Section at

gut. Fifteen months after operation the patient has had no hematuria or recurrence of the tumor. Cystoscopy shows no evidence of mental or other type of tumor and the ureterogram shows no evidence of filling defects. Further pathological study of the tumor showed a benign appearance and no indication of invasion.

In conclusion, therefore, it seems that surgeons should carefully consider any localized ureteral tumor from the clinical, x-ray, gross, and pathological aspects before they sacrifice the kidney. However any decision between nephroureterectomy and conservative management should be made by competent urological surgeons and pathologists.

JOHN W. BRENNAN, M.D.

Jewett, H. J.: Ureterointestinal Anastomosis In Two Stages for Cancer of the Bladder. *J. Urol.*, Balt., 1944, 53, 136.

The accumulated experience of the last thirty years has shown that a number of uncontrollable factors may arise after the Coffey operation and nullify the effects of a perfectly executed procedure. Therefore the author attempted to develop a method which would reduce these uncontrollable complications to a minimum, and would give consistently good results when properly executed.

His two-stage procedure had its inception in the experimental laboratory. None of the author's dogs survived any appreciable time after bilateral transplantation by the Coffey method, but after bilateral transplantation by this two-stage method, the dogs recovered rapidly and survived for indefinite periods. One can hardly fail to see the existence of an added factor of safety afforded by the two-stage principle, which allows the newly implanted ureter to heal as a graft in an aseptic bed before complete communication is established. This factor of safety is sacrificed in the Coffey operation.

The results in the series of 33 cases, completed during the last four years have demonstrated the soundness of the basic principle involved in this two-stage method of ureterointestinal anastomosis. When properly executed, subsequent hydronephrosis has been the exception rather than the rule and even in those instances in which some dilatation did occur ascending infection has been infrequent, if it did not exist prior to ureteral transplantation.

The author modified his original technique. The implantation is made exactly as originally described, except that the seromuscular flaps are approximated over the imbedded ureter by interrupted sutures of No. 0000 chromic catgut, with an atraumatic needle, instead of by continuous suture. (The latter sometimes caused a shortening of the bed.) The sutures should be drawn fairly taut, so that a naked strand of catgut will not cut into the underlying ureter and cause urinary extravasation. One must avoid piercing the intestinal mucosa with the needle, and compressing or constricting the ureter at any point. Adhesions causing rigid fixation of the sigmoid (containing the implanted ureter) to the poste-

rior pelvic wall have been much reduced by a modification of the original technique of the first stage. Some fixation of this portion of the sigmoid is desirable, in order to prevent kinking, stretching, and twisting of the ureter. Complete fixation, however, as originally advocated, by extraperitonealization of the site of implantation is unnecessary and in some cases has made adequate mobilization and delivery difficult at the second stage. The principal modification of the technique of the first stage consists in the abandonment of this extraperitonealization. Adequate immobilization is accomplished by apposing the serosa of the bowel to the serosal surface of the posterior parietal peritoneum. Adhesions thus formed are readily separated at the second stage.

The author emphasizes the following important facts: (1) a thorough search for metastasis should be made before operation, and chest films must be accurately interpreted; (2) excessive traction of the emerging ureteral stump must be avoided; (3) the patency of the ostium must be properly tested; (4) the ureteral stump must be adequately secured; (5) preoperative deep x-ray therapy may make closure of the peritoneum after cystectomy impossible; (6) preoperative renal infection may cause fatal urosepsis after transplantation, and (7) patients should not retain urine in the bowel longer than four hours, and should have satisfactory movements each day.

Modification of the operative technique of the two-stage method of ureterointestinal implantation has simplified the procedure.

The most important measures to be adopted at the first stage are: (1) prophylaxis of adhesions; (2) proper fixation of the sigmoid containing the ureter—at the second stage: (a) adequate mobilization of the sigmoid containing the ureter; (b) calibration of the intramural ureter; (c) avoidance of tangential cut with electrodes; (4) establishment of ostium of adequate length; and (5) prevention of subsequent leak from emerging ureteral stump by treatment with phenol and alcohol and by triple ligation.

No statement is made in regard to ultimate cure because less than five years have elapsed since total cystectomy in all of the cases of carcinoma of the bladder.

JOSEPH K. NARAT, M.D.

BLADDER, URETHRA, AND PENIS

Hess, E., and Wright, B. W.: Pyelocystostomosis: Report of Two Cases. *J. Am. M. Ass.* 1943, 137, 267.

The authors report 2 cases of direct anastomosis of the kidney pelvis to the urinary bladder—the first in a boy nine years old who had a huge hydronephrosis in the left half of a horseshoe kidney which could not be relieved with the cystoscope. Fourteen years later he was perfectly well with a normal urinary output and had no symptoms.

The second case in a patient of forty-two was diagnosed as hydronephrosis in a congenital ectopic

Fig. 1. 1 Bladder and hydronephrosis exposed through a midline incision. 2 Line of incision in the posterior wall of the bladder and the incision in the pelvis. 3 Relationship of the incision in the posterior wall of the bladder and the nephrotic pelvis. 4 Method of anastomosing the pelvis to the bladder.

solitary kidney. The condition was relieved by ureteral catheterization. Three weeks later the patient again had an acute hydronephrosis and 6 oz. of urine was drained from the hydronephrotic pelvis. Thirteen days later an attack of hydronephrosis was accompanied by severe colicky pain in the lower abdomen and suppression of the urine. The nonprotein nitrogen was 106.0 and the creatinine, 7.2 mgm. per 100 c.c. His blood pressure had risen to 210/110 as compared to 132/94. He had a severe headache, visual disturbance, vertigo, mental dullness and hallucinations with an obviously impending uremia.

At surgery, the ectopic kidney could be seen and felt beneath the posterior peritoneum in front of the first portion of the sacrum. A careful search failed

to reveal another kidney or a missing testicle. The right ureter was a blind pouch; the left ureter entered the hydronephrotic pelvis on its upper left anterior surface and was sharply angulated at the ureteropelvic junction. The long axis of the kidney was horizontal. The blood supply to the kidney was typical of that seen in ectopias and came from the abdominal aorta.

The posterior parietal peritoneum was incised in the midline and stripped from the kidney and the posterior wall of the bladder. The lower border of the renal pelvis was first attached to the lower part of the posterior wall of the bladder by several interrupted sutures of catgut, the purpose being to protect the anastomosis from undue tension. An extraperi-

last biopsy specimen was taken one hundred and twenty days after treatment with a total dosage of 1.145 mgm. of diethylstilbestrol given in average daily doses of 17 mgm.

The progressive changes depicted in this series of photomicrographs consisted of a proliferation of the epithelium of the ducts, the cells of the ducts increasing in their thickness from one to fifteen or more," and becoming elongated and finally portraying a process of budding—at times six or more buds could be found developing on the one duct which was present before treatment. There was also evidence of an increase in the connective tissue stroma, vascularity and periductal edema, and, finally in a section from another male breast, fat deposits were present, the subject having had 680 mgm. of diethylstilbestrol (an average of 1.4 mgm. per day for 485 days). The epithelium of the ducts along with its proliferations showed large cells of various shapes and sizes. The duct cells at times were multiplied to such an extent as to occlude the lumen, however

the cells were deeply staining and the basement membrane remained intact everywhere and was not invaded by the cells of the epithelial proliferative process. Indeed the authors stressed the fact that they had as yet observed no malignant changes in the breast from treatment with diethylstilbestrol and rather doubted if they would ever be found.

In concluding, the authors stated that the breast enlargement grossly as well as the breast proliferation microscopically is no indication as to the amount of benefit the patient is receiving with regard to the cancer of the prostate gland, and that the breast changes, although not serious in themselves are dangerous in that the patient often stops taking diethylstilbestrol when the breast pains begin or when they become severe. As yet the authors have observed no patient who was benefited more by orchiectomy than by the administration of diethylstilbestrol; they reserve the surgical procedure for those not benefited by endocrine therapy.

JOHN W. BARNHAM, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Dickson F D: The Clinical Diagnosis, Prognosis, and Treatment of Acute Hematogenous Osteomyelitis *J Am Med Ass* 1945 127 212

The prognosis and treatment of acute hematogenous osteomyelitis is discussed with the view that actually two separate and different syndromes are labeled with the same name. Both types of acute hematogenous osteomyelitis are initiated by a bacteremia and, in accordance with the course which the bacteremia takes, three different results may occur (1) the organisms in the blood stream may be destroyed (2) the organisms may lodge in bone, localize, and set up an osteomyelitis and (3) the bacteremia may become a septicemia with the formation of multiple abscesses in the lungs, kidneys, spleen, liver and the bones.

No matter under what circumstances organisms (staphylococci, streptococci, pneumococci) find their way into bone, a destructive process is set up. The reason why these abscesses occur predominately in the metaphysis of the bone is not known. The theory that multiple traumas are responsible for this occurrence proved to be incorrect. Fraser stated that in this area a great amount of reticuloendothelial tissue is found and as this acts as a defense mechanism, an infection is forced to localize in this area. Once the bacteremia has localized in bone areas, endotoxins are liberated and they destroy red cells, coagulate plasma, and cause the death of leucocytes. Because of the lack of the elasticity of bone the process spreads rapidly. A thrombosis of vessels occurs and there is less opportunity for the leucocytes to wander to this region to overcome the infection. Because of proteolytic toxins, the bone is autolyzed and partially destroyed and therefore, dead bone is found in these areas.

The clinical picture varies with the type of acute hematogenous osteomyelitis. Predominately children or adolescents are affected. In the usual case the first symptoms are pain, stiffness, and limitation of motion of the affected part. The temperature rises to between 102 and 104 F with a pulse rate of from 120 to 130 per minute. Restlessness and exhaustion due to the associated toxemia occur. Dehydration might occur with a persistently high temperature and decreased fluid intake. Localization of the process sooner or later occurs, and the affected region becomes swollen, hot, red and edematous.

The second type is initiated with a chill, and a rapid rise of temperature and delirium very frequently develop. These patients suffer from a septicemia with an associate formation of abscesses in various organs of the bones. Abscesses in bone seem to be only incidental to the existing pyemia. The

laboratory findings are characterized by a leucocytosis with a cell count ranging from 15,000 to 20,000. In most of the cases the blood culture is positive and anemia develops in the later stages of the disease. The antitoxic titer for staphylococci is important for the estimation of the natural defense of the patient and is found to be high in chronic osteomyelitis. It usually is higher in adults and rather low in infants. In making the diagnosis of acute hematogenous osteomyelitis, pyarthrosis, cellulitis, and in some instances, rheumatism have to be considered.

The prognosis of acute hematogenous osteomyelitis depends upon the type. In the first type the prognosis is good. In the second type the mortality is 50 per cent, perhaps higher. As far as the local bone focus is concerned age is the important factor. A great majority of patients three years or older pass on to the chronic stage. In infants the disease has very little tendency to become chronic.

At the present time there is considerable controversy as to the proper treatment of acute hematogenous osteomyelitis. This confusion exists because up until the present time no one tried to differentiate these two definitely different groups. In the first type the picture is that of a local infection associated with concomitant constitutional symptoms. In infants, that is, in children under two years of age, the treatment should be conservative and the general care of the patient rather than the osteomyelitis is the important consideration. With the use of sulfonamides, penicillin, and antistaphylococcus serum the disease quite readily becomes localized. The delicate periosteum usually breaks and the pus escapes into the surrounding tissues. If indicated, a small opening is made to allow the pus to escape. However, the less surgery done, the more favorable is the prognosis. During the treatment of patients two years of age or more, more bone destruction takes place and the tendency for the acute condition to become chronic is very great.

General supportive measures—chemotherapy, the administration of staphylococcus antitoxin, and management of the local bone disease—are indicated in the treatment of the second type of acute hematogenous osteomyelitis.

Shands and Baker used staphylococcus antitoxin quite extensively and their reports are quite favorable in cases of staphylococcus septicemia with high toxicity. Treating a bone abscess conservatively with sulfonamides alone is using bad judgment. It has been repeatedly shown that definite areas of bone destruction, as shown on roentgenograms, harbor organisms that often cause these areas to flare up with a recurrent attack of acute osteomyelitis.

The author advocates the use of chemotherapy in conjunction with local drainage of the bone abscess by removal of a block of bone and allowing the pus

to escape through an incision in the soft tissues that is kept open with vaseline packs or by the use of the Dakin-Carrell treatment. *George L. Russ, M.D.*

Holt, J. P., and Hodges, F. J.: Significant Skeletal Irregularities of the Hands. *Radiology* 1945 44 23

The authors believe that careful roentgen study of the hands may furnish as valuable information to the radiologist as funduscopic examination does to the ophthalmologist. In reviewing some of the significant abnormalities they lay particular stress upon those carpal, metacarpal, and phalangeal changes which reflect the presence of disease elsewhere in the body.

Endocrine diseases. A good example is the roentgenographic appearance of the hands in acromegaly which indicates the presence of a pituitary eosinophilic adenoma even in the absence of erosion of the sella. Large, broad, spadelike hands with overgrowth of the terminal phalangeal tufts, prominence of bony protuberances along the shafts of the metacarpals and phalanges, and peculiar soap-bubble pattern of distorted trabeculae in the bone ends comprise the changes commonly encountered. In cretinism the delayed epiphyseal ossification and the increased density in the ends of the tubular bones such as one might expect to see in lead poisoning or osteopetrosis, dominate the picture. A knowledge of these changes also helps to differentiate cretinism from mongolian idiocy in which the bone development is relatively normal but the hands may present fairly typical anomalies as, for example, congenital shortening of the middle phalanx of a stubby curved fifth finger. Other abnormalities are the fibrocystic bone lesions of hyperparathyroidism and polyostotic fibrous dysplasia, the peripheral degenerative changes of progeria, and so forth.

Genitalia males. In dysostosis cleidocranialis, in addition to the defective ossification of the bones laid down in membrane, there are characteristic alterations of the hands. The ungual phalanges are short and cone shaped with failure of development of the usual prominent cancellous tufts. The metacarpals, as well as the proximal and middle phalanges, have supernumerary epiphyses which fuse much earlier in life than the normal ones. All epiphyses appear broader than normal. In the hands of the achondroplastic dwarf the second to fifth metacarpals are short, stubby and of nearly equal length. As in the case of the long bones, their ends may be quite bulbous. The phalanges likewise are extremely short and relatively broad. In Morquio's disease the ends of the metacarpals and phalanges are grossly irregular and the carpal bones have a striking crenated appearance. In Hurler's syndrome (gargoylism) the metacarpals are unusually short and broad, the middle phalanges have an arrowhead configuration, and the trabecular pattern is very coarse. Arachnodactylia, or spiderlike fingers, immediately focuses the attention on congenital dislocation of the lenses with congenital heart disease.

Trophic disturbances. These may reflect syringomyelia, leprosy, Raynaud's disease, erythromelalgia, thromboangiitis obliterans, arteriosclerosis, diabetes, scleroderma, and acrosclerosis.

Chronic granulomas. Spina ventosa is a characteristic manifestation of tuberculosis. Osteitis tuberculosa multiplex cystica, as described by Juengling, is another tuberculous manifestation which occasionally is associated with Boeck's sarcoid. Granulomatous lesions produced by pathogenic fungi may also involve the metacarpals and phalanges.

Pulmonia y osteoarthritis pathy. Clubbing of the terminal phalanges with roentgenographic evidence of periosteal proliferation along the shafts of the metacarpals and phalanges is always indicative of pulmonary disease. In fact, its variation in the same individual under the influence of pulmonary therapy carries definite prognostic significance.

Hemopoietic and blood diseases. In this group hemophilia, leucemia, chronic hemolytic anemia, and rarely sickle-cell anemia and chronic hemolytic jaundice may produce diagnostic roentgenographic signs in the hands.

Miscellaneous lesions. Other conditions that may lead to changes in the bones of the hands are osteoarthritis, gout, chondromas, solitary cysts, osteopikilosis, osteopetrosis, melorheostosis, and tuberous sclerosis.

Typical roentgenograms are used to illustrate most of these changes. *T. Livcunia, M.D.*

Sarpyner, M. A.: Congenital Stricture of the Spinal Canal. *J Bone Surg* 1945, 23 70.

The author differentiated 4 congenital strictures of the spinal canal (1) a ringlike constriction of the spinal cord at one or more levels (2) more extensive strictures involving the entire canal (3) a localized stricture and (4) atypical strictures, causing a cleft in the cord in both the cord and dura mater.

Constrictions of the cord in spina bifida occulta were found regularly. The clinical manifestations of a stricture compressing the spinal cord are manifold: enuresis, pains similar to those in lumbago and sciatica, atrophy of the muscles, skin changes similar to vitiligo perforating ulcer, spastic or flaccid paralysis, and various deformities. These patients do not suffer pain because these conditions, like certain spinal tumors which grow slowly exist for a number of years and exert only gradual pressure on the cord. In several patients suffering from enuresis, a lipoidal block was found at the level of the second and third lumbar vertebrae. These patients were not helped by any conservative measures. A definite constriction was found at the level of the second and third lumbar vertebrae at the operation, and upon release of the constriction immediate cure of the enuresis followed. It is also stated that many club feet, several of them of the paralytic type, were cured by laminectomy and release of the congenital stricture of the canal.

X ray films and photographs are presented to illustrate the pre- and postoperative conditions of

the patients. A short outline of the technique of aminectomy is given. In cases of spastic diplegia 5 or 6 vertebrae should be included in the operative field. The stricture must be completely relieved and pulsations must return to the dura below the level of the lesion. In cases of spina bifida it is important not only to remove the tumor but also to relieve the stricture, because if this is not done agenesis of the nerves will continue.

GEORGE I. REISS, M.D.

Kaplan, E. B.: The Surgical and Anatomic Significance of the Mammillary Tubercle of the Last Thoracic Vertebra. *Surgery* 1945 17 78.

Two tables and 8 figures represent in detail a study of the anatomic significance and surgical importance of the mammillary process of the twelfth thoracic vertebra. The mammillary process on this vertebra was found to be large and prominent. This process conceals the upper articular process of the twelfth, and the inferior articular process of the eleventh thoracic vertebra. It represents a good point of localization of the twelfth thoracic vertebra in surgery of the spine. In operations for fusion of the spine involving the eleventh and twelfth thoracic vertebra, the removal of the mammillary process of the twelfth vertebra will allow the proper removal of the cartilage of these facets.

RICHARD J. BENNETT, JR., M.D.

Dandy, W. E.: The Treatment of Spondylolisthesis. *J. Am. Med. Ass.* 1945 137 137.

It is difficult to believe that other discs than the one at the site of the spondylolisthesis are not always affected when the spinal column is thrown out of line by this condition. In this series the concealed discs numbered 33 (75 per cent) as against 11 (25 per cent) that were protruding. This is essentially the same ratio that obtains in discs without spondylolisthesis. Thirteen patients were males and 7 females.

It is the author's impression from his analysis that spondylolisthesis is but an incident in the field of ruptured discs and that, on the whole, while it causes its share of symptoms, it causes less than the contiguous disc or discs. Any treatment that neglected the other discs would accomplish little if any result. Moreover the reason for the development of spondylolisthesis is precisely the same as that for defective discs, i. e. the outward shift in the lateral articulations in the lower three lumbar vertebrae, nearly always most pronounced at the fifth lumbar vertebra. And finally the signs and symptoms of spondylolisthesis are precisely the same as those of defective discs without spondylolisthesis. Only the x-ray appearance makes the differential diagnosis.

If a disc is thoroughly and painstakingly removed with a curet, it cannot recur. This does not mean that every particle of cartilage must be extirpated but it does mean that no large amount can remain. The area of the disc most difficult to remove is dorsal on the contralateral side, and a recurrence with scoliosis on the opposite side will occasionally occur.

In at least 90 per cent, and probably in all of the cases, there are two or three discs (including the one at the site of the spondylolisthesis) which cause the backache and sciatica, and a cure depends on the recognition and treatment of all the affected discs. The disc at the site of the spondylolisthesis causes no more symptoms than the other discs; in fact, on the whole, it causes even less.

A cure results when the discs are completely removed. The end result of removal of the discs is fusion of the opposing vertebrae and, therefore, stabilization of the spine. This obviates the necessity of fusion by means of bone grafts to the spine. Statistics on the results are presented.

Spinal fusion by grafting is never indicated either for spondylolisthesis or for defective intervertebral discs. Its continued use means that the discs have been improperly recognized or treated or both.

ROBERT P. MONTGOMERY, M.D.

Green, W. T.: Slipping of the Upper Femoral Epiphysis: Diagnostic and Therapeutic Considerations. *Arch. Surg.*, 1945, 50 19.

The author reports 26 cases of slipping of the upper femoral epiphysis or epiphysiolysis. The total number of hips involved in these cases totaled 36. They represented all slipped femoral epiphyses seen by the writer in thirteen and one half years.

The mechanism is that of an insidious inherent weakness developed between the head and neck of the femur at the metaphysis which results in a downward displacement of the head and an upward and anterior displacement of the neck. Derangement varies from an undetectable degree to a complete epiphysal separation.

The etiology is obscure. It affects both sexes between the ages of ten and fifteen years. Obese children are more susceptible. Other factors are trauma, endocrine disturbances, periosteal insufficiencies, and vascular abnormalities about the femoral neck.

The clinical picture is one of an obese child who acquires an antalgic hip limp, pain in the homolateral knee or hip, limitation of internal rotation, flexion and abduction, hyperextension of the involved hip and muscular spasm.

Röntgen examination discloses rarefaction of the neck adjacent to the epiphysal line and (early) minimal displacement of the femoral head. Irregular callus may be noted if the slipping is of long standing.

The author employed 5 different forms of treatment among the 36 hips.

1 Closed reduction with spica fixation. Three cases were treated with satisfactory results.

2 Traction spica method without manipulation. Eighteen hips in 13 patients were restored to excellent function. While there was an average shortening of 1 cm. in the treated hips a normal coefficient of motion of 98.5 was attained in the majority of cases.

3 Skeletal fixation *in situ* (without arthrotomy) for those hips with minimal displacement. Five hips were so treated by means of a modified Smith-Peter

seen. While the results were classified as good, there was a diminished coefficient of motion, i.e., from 80.5 to 84.5. One of the 5 patients suffered further displacement of the epiphysis following operation from excessive growth of the neck.

4. Open reduction with skeletal fixation was reserved for those hips with pronounced derangement. The results in 3 of the 4 hips treated in this manner were classified as poor. In the other 3 cases excellent functional results were obtained after modification of the operative procedure.

5. Miscellaneous methods, including traction, non-weight-bearing brace, and crutches were used in the remainder of the cases.

Operation includes preservation of the periosteum about the neck, meticulous care of the inferior cervical vessel (reticula of Weitbrecht), removal of the soft osteoid, restoration of normal alignment, and firm fixation. The author prefers the Moore type of nail. Arthrolysis is accomplished through a lateral exposure.

SAMUEL L. GOVERMAN, M.D.

Cox, F. J.: Traumatic Osteochondritis of the Patella. *Surgery* 1945 17 93.

When a direct blow to the patella is received the patella is driven against the adjacent femoral condyle and a greater or lesser degree of compressive force is exerted upon the subchondral bone. This causes the development of areas of necrosis in the subchondral bone of the patella and femoral condyles which can be considered in almost the same light as a fracture. If the initiating trauma is mild and the amount of damage to the subchondral bone is minimal spontaneous absorption and repair of the involved bone may occur. If, however, the area of necrosis in the subchondral bone is more extensive, the area of involved bone is walled off and becomes a true sequestrum. Immediately gross interference with the nutrition to the overlying articular cartilage layer develops, and consequent degenerative changes in that cartilage begin to appear. When these changes persist for a period of time, thinning of the articular cartilage of the patella, irregularities in contour and fissures may occur. As a later manifestation the synovium of the knee joint becomes irritated. In response to this irritation hypertrophy of the synovium and a chronic effusion result. Should the lesion remain untreated for a period of years, progressive arthritic changes in the knee joint will be found. The lesion is certainly not uncommon.

The author presents 6 examples of this condition that have come to his attention.

In all cases except 1 a direct injury to the patellar region was established which forced this bone against the anterosuperior surface of the medial femoral condyle. This resulted in immediate temporary disability caused by local swelling and pain upon flexion or extension of the knee joint.

The acute symptoms referable to the knee joint subsided for several weeks or months. With the passage of time there appeared a low grade chronic effusion which fluctuated in degree with the extent

and character of exercise indulged in by the patient. Definite vague symptoms of discomfort persisted within the knee joint and vague pain was felt on its anterior aspect. This sometimes was made worse by exerting strain upon the flexed knee through the quadriceps apparatus as when kneeling or squatting. All of the patients complained of occasional symptoms of locking, or "catching." The condition was chronic.

The following gross pathological changes were noted at operation: (1) softening irregularity in contour and fissure formation in the articular cartilage of the patella. (2) yellowish discoloration of the articular cartilage in the areas of involvement. (3) similar changes in the articular cartilage of the femoral condyle on its anteromedial aspect. (4) thickening, hyperemia, and villous degeneration of the synovium, usually confined to the suprapatellar pouch region and the anterior compartment of the knee joint. (5) increase in the amount of the joint fluid, usually clear yellow in color with a normal cell count, or slight increase in polymorphonuclear cells and (6) pannus formation at the edges of the articular cartilage of the patella and femoral condyles.

In the author's opinion the true pathological change is to be found in the underlying cancellous bone, and the change in the articular cartilage is an entirely secondary one. All cases in the literature emphasize the cartilaginous changes.

All of the 6 patients treated by excision of the patella, with the synovium and degenerated femoral cartilage left undisturbed made complete recoveries, with disappearance of the synovitis and effusion in every instance. Some other factor may well be the cause of the late development of arthritic change. Removal of the involved cartilage alone has caused subsidence of the synovitis and secondary joint changes. Patellarplasty has given good results, although apparently not quite as good as patellectomy. The author is not completely convinced that removal of the patella in the human being will lead to arthritic changes in later life. Although there is no definite proof at this time it is believed that the more severe and permanent changes resulting from an osteoarthritis have been obviated in this group of patients by removal of the patella. The lesson, as described is rare by admission, but perhaps not so rare as it might seem at first glance. If the under surface of the patella were routinely inspected in every exploratory operation for internal derangement of the knee joint, probably more cases would be encountered.

ROBERT P. MONTGOMERY, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Jones, L.: Complete Rupture of the Supraspinatus Tendon: A Simplified Operative Repair. *Arch. Surg.* 1944, 49 390.

This article is based upon a series of 51 cases of painful shoulder among which were found 3 cases of complete rupture of the supraspinatus tendon. The

lines of force which pass through the musculotendinous cuff are present in aggravated form at the circular portion of the supraspinatus tendon just above the point of final attachment to the horizontal line of the greater tuberosity of the humerus. When rupture once occurs in this weakened area there is a retraction of the edges due to the pull of the force from four directions—superior inferior anterior and posterior. Even the dependency of the arm helps to keep the rent open. Nature attempts to heal this defect by scar tissue often associated with a calcium deposit. A low grade inflammation is often present.

Three cases of complete rupture of the supraspinatus tendon were repaired by a new operative procedure. On the basis of cases in which the head of the humerus has been discarded and the capsule has been reattached to the upper end of the shaft by means of bony grooves, a stable shoulder results. When these grooves are arranged in a physiological pattern the stability is accompanied by nearly complete functional recovery. The short rotator or capsular muscles are considered in three groups. They are (1) the subscapularis (2) the supraspinatus and (3) the infraspinatus and teres minor muscle. These fuse with the capsule of the shoulder joint before a final bony insertion to form a conjoined tendon. The supraspinatus inserts into the transverse line of the greater tuberosity. The infraspinatus-teres minor group inserts into the posterior descending line. The subscapularis group inserts into the lesser tuberosity of the humerus and the anterior border of the bicipital groove. This group of three muscles working together constitutes an antagonist for the deltoid muscle. The combined weight of these three is approximately the same as that of the deltoid muscle. The complete loss of abduction cannot be due to the loss of the supraspinatus muscle alone. These three powerful muscles pull not only against the bony insertions but against each other through their central junction in the conjoined tendon. The presence of a central supraspinatus-tendon rupture definitely produces inaction of the neighboring muscles, specifically the subscapularis in front and the infraspinatus-teres minor muscle in back. From these anatomic facts it seemed reasonable that a flap from the contiguous upper portion of the infraspinatus muscle could be transplanted as a substitute for the ruptured and retracted tendon of the supraspinatus muscle. In a large defect two flaps were used one from the infraspinatus and the other from the subscapularis.

The first patient was a female, age twenty-six with pain in the left shoulder of seven years duration. There was a definite injury followed by pain which persisted. The patient had been treated conservatively for a subacromial bursitis. Diagnosis of rupture of the supraspinatus tendon was made. Manipulation of the arm was necessary during operation to facilitate fixation and closure. A Cubbins acromioclavicular incision was used. The deltoid muscle was elevated and incised close to its attach-

ments. The anterior two-thirds of the deltoid muscle were reflected downward as a flap. A complete rupture of the supraspinatus tendon was found. A 1 inch transverse groove was made on the lateral surface of the humerus just below the transverse line of the greater tuberosity. Two drilled holes were made at each end and at right angles to the end of the groove. The infraspinatus muscle was fixed into the groove by means of silk suture. The edges of the transplant were sutured to neighboring muscles to re-establish continuity. An abduction splint was used with the arm maintained at 60 degrees. The patient had complete return of function after four months.

The second patient was a male, age seventy who after injury was unable to abduct his arm. He was given physical therapy. During operation, and after the deltoid muscle had been reflected, a tear was visualized which involved the three groups of muscles. It is better described as a complete avulsion. Here two bony grooves were made one transversely and one vertically and it was necessary to supplement them with a piece of fascia. The subscapularis was sutured into the anterior groove, and the infraspinatus-teres minor and supraspinatus were sutured into the vertical groove. Closure was made by means of a fascial continuous running suture. The edges of the flap were sutured to each other and continuity was re-established. The patient's arm was abducted 45 degrees on a splint and no movement was allowed for six weeks. Seventeen months later the patient had a completely painless shoulder with abduction to 60 degrees.

The third case was that of a male age sixty who suffered severe injury. Avulsion of the upper capsular segment was found to be quite extensive. A very similar operative procedure to that used for the second patient was employed. Eleven months after injury the patient was able to abduct his arm to 90 degrees.

RICHARD J. BENNETT, JR., M.D.

Aitken A. P.: Stenosing Tendovaginitis at the Radial Styloid Process (De Quervain's Disease). *N. England J. M.*, 1945 332 105.

De Quervain's disease is caused by a thickening of the tendon sheath covering the abductor pollicis longus and extensor pollicis brevis as they pass over the radial styloid process. This disease is seen in women much more frequently than in men. It may be present for several months and then become acute, following a trauma. It is rarely seen in persons over twenty five years of age. It often occurs in cooks, nurses, and housewives. Finkelstein described a test which is pathognomonic for this condition.

The thumb is placed in the palm of the hand and the forefingers are flexed tightly over it. Ulnar deviation of the hand then causes severe pain over the radial styloid process, but radial deviation causes no discomfort.

Fractures of the carpal navicular have to be differentiated from De Quervain's disease. In fractures

Fig. Diagram showing the location of the fibrous sheath at the radial styloid and the divergence of the short extensor and long abductor on abduction or extension of the wrist.

of the navicular there is pain in the anatomical snuffbox, and motion and movements of the thumb are not as painful as in De Quervain's disease.

The treatment of choice is surgery. An incision about 4 cm. in length is made over the tendons at the level of the radial styloid process. The tendon sheath is opened, fibrous thickened tissues, as well as adhesions, are excised and only the skin is sutured. Motions are started the day following the operation. No recurrences have been seen. Keloids have developed in the incisions because of encouraged early motion following the operation.

GEORGE L. REISS, M.D.

Smith Petersen, M. N., Larson, C. B., and Aufranc, O. E.: Osteotomy of the Spine for Correction of Flexion Deformity in Rheumatoid Arthritis. *J Bone Surg* 1945 8

In osteotomy of the spine the operative procedure is confined to the laminae and articular facets and does not involve the vertebral bodies.

Recumbency in the position of minimum pain commonly results in a flexion deformity of the spine sufficiently marked to interfere with the function of the lower extremities in standing and walking and to make the sitting position one of strain and discomfort.

Manipulation, followed by support, will improve many of these patients but it will not be of benefit after bony ankylosis of the articular facets and calcification of the longitudinal ligaments have occurred. Patients with ankylosis of both hips not infrequently present this latter extreme condition of the spine.

After arthroplasties the flexion deformity of the spine interferes to such an extent with function of the lower extremities that the problem of correction becomes most important. Analyzing the obstacles to correction, the authors came to the conclusion

that the ankylosed facets surrounded by overgrowth of bone offered more resistance than any of the other spinal structures.

Any surgical procedure for correction of the flexion deformity must, therefore be aimed at the facets, articular processes and adjacent laminae, osteotomy of these structures, with excision of sufficient bone should allow corrective leverage to be transmitted to the intervertebral discs and longitudinal ligaments, and overcome whatever resistance they may present.

Surgical intervention in rheumatoid arthritis should be undertaken early before secondary deformities develop.

The lumbar region is more favorable than the thoracic since the latter commonly presents ankylosed costovertebral joints which make correction difficult, if not impossible. Thoracic osteotomy was done in only 1 case; it resulted in subjective improvement, but there was no objective evidence of it.

Selection of the lumbar level or levels at which the osteotomy is to be performed depends on the roentgenographic findings, the less marked the ossification the better the chance of correction.

A description of the operative technique with special emphasis upon aspects that are likely to cause technical difficulties is presented.

In the postoperative care a plaster shell is applied and kept on for from four to six weeks; this is followed by a plaster jacket or back brace which is to be worn continuously for a year or longer. Since complete correction is never obtained it is important to guard against recurring deformity by having the patient wear the brace during part of the day for two or three years postoperatively. It is hardly necessary to emphasize the importance of exercises for the control of posture as well as for the maintenance of chest expansion.

The author states that osteotomy of the spine, performed in a series of 6 cases, has yielded satisfactory results.

ROBERT P. MORRISON, M.D.

Boerworth, D. M.: Clothespin Graft of the Spine for Spondylolisthesis and Laminar Defects. *Am. J. Surg* 1945, 67 6

The clothespin graft consists of a bone graft with the ends notched out to receive spinous processes at either end of the fusion area. During placement the patient is in flexion with the spinous processes separated. Following operation the patient is extended and the graft is maintained firmly in position.

The intervertebral laminae of the graft area were definitely enlarged and apparently reduction of the vertebral body in spondylolisthesis was secured. Decompression of the nerve roots and immediate relief of the compression pain were also obtained. The first grafts were of tibial bone; later massive iliac bone grafts were used. These single fusions were reinforced with separate iliac strips. Forty-seven cases were operated upon with 1 mortality. Fracture

Fig. 1. Double clothespin graft has great strength, is firmly maintained in position when applied with the spine in flexion and then extended to normal, and provides a distracting force to separate intervertebral spaces as well as secure fusion. Note the opening of the third lumbar intervertebral space and separation of left fifth lumbar and first sacral articular facet caused by long clothespin graft as shown in roentgenograms. (Courtesy of American Journal of Surgery)

of the body of the graft has not occurred but there were postoperative infections. Two grafts were removed for aseptic necrosis; the cultures were negative and primary healing followed removal. Spontaneous fracture of the tibia at the site of osteotomy occurred in 4 instances. The spinous-process abutment on the sacrum was dislodged by graft compression

in 3 instances postoperatively. Several complications accompanied these procedures. Hospitalization varied from twelve days to four months. Among the uncomplicated cases the average time of hospitalization was three weeks. Plaster jackets were applied two and one half weeks postoperatively and these were worn for five months.

Several variations of this clothespin graft have been used. There were numerous variations of the area grafted. Several conditions were listed for which the operation was performed. Fifty-five patients were operated upon before January 1943. Clinically there was solid spinal fusion in 49 cases (89 per cent) there were 4 clinical failures. It is believed the only accurate method of determining solid spinal fusion is by flexion and extension x rays. Thirty-three of 41 cases have been checked with these, most of the x-rays showed the fusions to be completely solid. Among 11 instances of spondylolisthesis, 8 fusions were proved to be solid by x ray studies. Among these there was 1 failure. Clinical relief was obtained in all of the patients except 4 who were partially relieved and 4 others who were unrelieved. These failures are analyzed.

RICHARD J. BROOKETT JR., M.D.

Thompson, T. C., and Alldredge, R. H.: Amputations; Surgery and Plastic Repair. *J Bone Surg* 1944, 26 639.

The guillotine operation has many advantages, especially under wartime conditions.

1. It is a simple débridement of the end of the extremity easily accomplished under adverse conditions.

2. It is rarely followed by spreading infection in bones or soft parts.

3. It saves more extremity than any other method.

4. If skin traction is soon applied and maintained until the patient arrives at the Amputation Center preparation of a satisfactory stump is simple.

Its advantages are

1. No devitalized tissue is left in which infection will persist or spread.

2. The raw surface exposed is not large, and has a good blood supply.

3. If the skin traction is constant the scar formation at the end tends to pull the soft tissues over the end of the bone and results in a firm, smooth, conical stump.

4. Repair necessitates only the excision of scar tissue and perhaps a small tip of bone, and normal skin and subcutaneous tissue are easily fashioned and closed without tension.

5. These stumps are as good as those obtained by primary amputations at sites of election and can be quickly fitted with a prosthesis. When revision of the stump is necessary it heals promptly with rapid shrinkage of the stump.

6. The frequent complications of primary or early secondary closure are avoided.

The authors advise against the use of pin fixation above the site of a severe compound fracture if an attempt is to be made to save the limb, as amputation has eventually been necessary at the level of the upper pin. Otherwise amputation may have been at the site of fracture.

The time for revision or reamputation of a stump depends upon various factors. If the stump is short, skin traction should be maintained as long as healing

continues. The type of dressings should depend upon the type of organisms present. Sulfonamides are used preoperatively and postoperatively, and the administration of penicillin twenty-four hours before and fourteen days after operation permits excision of the scar and granulation tissue and even of sequestra for skin closure. When the bacteria are penicillin-resistant, wound infection should be controlled after sequestrectomy before closure is attempted.

In order to secure smooth skin margins without tension, the skin flaps must be undermined a considerable distance. Deep stay sutures are unnecessary as they often produce depressed transverse scars across the main scar. A rubber tissue drain is inserted at each end from one to three days. Post-operative skin traction is used when tension on the suture line from postoperative swelling is suspected.

Plastic repair should be performed on most guillotine stumps in order to provide the best possible stump.

ROBERT S. REICK, M.D.

Peterson, L. T.: The Army Amputation Program. *J Bone Surg* 1944, 26 635.

In May 1943 the Surgeon General directed the establishment of 5 Amputation Centers in various sections of the country for the purpose of co-ordinating and standardizing the treatment and fitting of amputees.

Early in the present war three difficulties were encountered in the treatment of amputations.

1. Primary closure is definitely contraindicated in military surgery as it is likely to cause cellulitis, osteomyelitis, or gas gangrene which may endanger the patient's life and may necessitate additional sacrifice of the extremity.

2. In some patients the guillotine operation had been performed higher than necessary either through or above the level of election for a finished stump.

3. Early and continuous skin traction is imperative in open amputation technique, as failure of adequate traction results in the retraction of the soft tissue. A skin graft is not an acceptable substitute as it does not ordinarily withstand the pressure of a prosthesis.

As soon as the stump has been properly treated by surgery and physical therapy it is fitted with an artificial limb. The Amputation Centers have completely equipped shops. On the lower extremity the amputees are fitted with a provisional prosthesis which may be refitted or adjusted later as required. On the upper extremity the prosthesis requires less change. The patient is fitted with the particular features which best suit his needs.

The statistics of this war indicate that 25 per cent of the total amputations resulted from training accidents, accidents not related to military activity, vascular diseases, and tumors. One amputee in 30 lost 2 extremities less than 1 in 300 was amputated at the hip joint, while amputations below the knee and elbow predominate. On admission, 361 patients (21.6 per cent) were ready for prostheses, while 1,399

(78.4 per cent) required further surgery before proper fitting was possible.

In addition the amputee with a prosthesis for the leg is taught how to walk by the physical therapist, while the amputee with a prosthesis for the arm is trained in the use of the attachments to this prosthesis.

RUDOLPH S. RICH, M.D.

FRACTURES AND DISLOCATIONS

Murray G.: Longitudinal Wires in Bones in the Treatment of Fractures and Dislocations. *Am. J. Surg.* 1945 67 156.

Longitudinal wires in bones have provided excellent fixation of certain selected fractures and in particular those fractures in which it has been difficult to obtain satisfactory fixation by external splinting either with or without skeletal pins.

In fractures of the clavicle, scapula, both bones of the forearm, some cases of fracture of the humerus and long bones of the hands and feet, it provides a method by which greatly improved results in these fractures can be expected. Acromio and coracoclavicular dislocations are easily controlled by this method. Naturally as in all procedures in which it is necessary to make an opening in the skin the most rigid aseptic surgical technique must be observed. In the author's experience there has been one infection in which it was necessary to remove the wire because of the infection.

In the humerus the wire is passed through the greater tuberosity and vertically down the shaft the wire is placed in an extra-articular position. Passed in this way it gives excellent control of fractures of

the high surgical neck or shaft. With such a wire in position the arm has been carried in a sling only and excellent union in a good position has resulted. In the forearm with fractures of both bones, the subcutaneous olecranon provides a very easy approach through which to pass the wire through the proximal and into the distal fragment. In the radius the subcutaneous styloid process offers an easy and extra-articular approach through which the wire can be passed through the distal and into the proximal fragment. If after reduction and fixation of the ulna with the wire the radius can be reduced it also is held by a wire. If however the fragments are so engaged that closed reduction is impossible a short incision over each bone should be made and accurate reduction obtained. The wires then passed as described, provide excellent fixation which is quite easy to apply. To date all such fractures have been fixed in plaster casts until evidence of union has taken place. In the metacarpals and phalanges when reduction has been obtained the wire can be passed in the case of the metacarpal it is passed through the distal articular end and across the fracture line into the proximal fragment, with the proximal phalanx flexed to an angle of about 45 degrees. If the fracture is at the neck or near the head of the metacarpal the wire is best passed through the distal articular end of the proximal phalanx through its medullary cavity across the metacarpophalangeal joint through the distal fragment, and well into the proximal fragment. In fractures of the phalanges after reduction the wire is passed either through the distal articular end of the affected phalanx or through the tip of the finger and across the interphalangeal

Fig. 1. Comminuted fracture of both bones of the forearm satisfactory result by wire fixation. (Courtesy of American Journal of Surgery)

joint, if necessary. In none of these fractures has there been evidence of any ill effect in the way of discomfort or disability as a result of the fine wire traversing the articular cartilages.

This form of fixation is the most satisfactory in fractures of the clavicle. In dislocations of the acromioclavicular joint, fixation by two or more wires gives a most satisfactory result with no permanent deformity.

With acromioclavicular and wide coracoclavicular separation, fixation of the acromioclavicular joint by wires also provides a very easy and effective method of allowing repair of the coracoclavicular ligaments with subsequent excellent stability and function of the shoulder girdle.

Longitudinal wires also provide an easy and excellent method of fixation of internal and external malleolar fractures at the ankle when closed methods of reduction are not satisfactory.

Use of wires in a similar way offers excellent fixation in arthrodesis of interphalangeal or metacarpophalangeal joints in the hand or foot.

In Cant's subtrochanteric osteotomy to correct an adduction deformity, the lower fragment tends to be displaced medially when the femur is divided across. The procedure is greatly facilitated and the fixation is adequate when a longitudinal wire is passed through the tip of the great trochanter and down the shaft of the femur.

A series of illustrative cases is shown by x rays that demonstrate the use of the wires and the end results obtained. This report is based upon 154 patients treated with longitudinally placed wires. None of the wires has drifted out of the field.

The presence of the wire across the fracture line has not impeded the rate of union of the fracture and there were no nonunions in this series. On the contrary in the majority of cases these fractures united in a shorter time than ordinarily would have been expected.

Longitudinal wires in bones have provided excellent fixation of certain selected fractures and in particular those fractures in which it has been difficult to obtain satisfactory fixation by external splinting either with or without skeletal pins.

There has been no evidence that a small or medium-sized Kirchner wire which traverses articular cartilage produces any deleterious effect on the joint. ROBERT P. MONTGOMERY, M.D.

Boonin, J. G.: Sacral Fractures and Injuries to the Cauda Equina. *J Bone Surg* 1945, 23 115.

The lateral portions of the sacrum are weakened by the first and second sacral foramina. Most of the fractures, therefore, occur in this portion of the body and sometimes spread from this portion to other areas of the pelvis, for example, to the innominate bones. Most of the sacral fractures are caused secondarily to pelvic injuries and by violence applied to one side of the body or one leg.

The sacral fracture might be caused by the following conditions

1. By a rotation injury. The hyperextended lower leg is pushed backward. The affected innominate bone is rotated in a horizontal axis which causes the fracture line to run through the first and second sacral foramina. This injury very often is associated with a separation of the pubic symphysis or a fracture of the ischiopubic ramus.

2. By leverage. The violence is transmitted through the abducted lower extremity. This usually occurs in run-over accidents.

3. By shearing force. One-half of the pelvis is driven directly backward by an impact against the knee of the patient in sitting position. In 45 per cent of all pelvic fractures the sacrum is involved. The sacrum is described in detail as it appears on routine anterior and posterior roentgenograms and certain important landmarks are pointed out.

The neurological signs are caused by compression of the first and/or second sacral nerve roots. These findings correspond with other conditions involving these nerve roots. Injury to these nerve roots may be caused by pressure of small fragments of bone, by surrounding hemorrhage, stretching, or by contraction of fibrous tissue or callus.

The most characteristic feature of sacral fracture extending through the first and/or second foramen is the distribution of muscle paresis. Paresis of the buttock, hamstrings, and calf muscles characterize the lesion, according to the author. Marked paralysis of the biceps femoris was observed in all cases and is probably the most distinctive sign in this condition. The loss of ankle reflex, combined with fibrillation of the calf muscles, is very often seen. In spite of the disagreement among authorities as to the different areas of the dermatomes supplied by the first and second sacral nerves, the following skin areas usually show sensory changes: a small area of hypesthesia to light touch and pinprick on the medial aspect of the left buttock with a surrounding area of hyperalgesia, hypesthesia or anesthesia of the back of the lower half of the leg, the outer side of the foot, and part of the sole. Similar findings are found in herniated nucleus pulposus. In this condition, however usually one single nerve root is affected.

The pain pattern of these two conditions can be considered as a differential diagnostic point. Pain in herniated nucleus pulposus which arises from tension on the nerve is more or less of a constant nature. The pain in sacral fractures is severe at the onset of the injury but rapidly subsides. This is due to the fact that in sacral injuries the nerve usually is severed. Bladder and bowel disturbances are infrequent because sacral fractures are usually unilateral.

The treatment consists of a counterbalanced sling around the pelvis of the patient with traction on the lower extremity and physical therapeutic measures. In the average type of sacral fractures the prognosis is good. There is usually complete recovery and only occasionally some weakness in the affected leg with slight permanent muscle wasting.

Case reports roentgenograms, and photographs of 5 patients with sacral fractures combined with pelvic fractures are presented
 GEORGE I. REISS, M.D.

Boucher, D. W.: Internal Fixation of Fractures of the Neck of the Femur. *Consil. M. Ass. J.*, 1945
 32-33

When severe pain persists after an accident involving the fracture of the neck of the femur internal fixation by nailing should be carried out as soon as possible. Preoperative extension has not been used and the author believes that fractures forty-eight hours old reduce as easily as those of a few hours duration. In handling these patients the anesthetic is usually nitrous oxide and oxygen given by spinal or local infiltration. When both surgeon and radiologist understand each other's abilities and problems the operative time is decreased.

The procedure consists primarily of anesthetizing the patient in the recumbent position, and Leadbeater's maneuver of reduction is carried out. After reduction the thigh is in abduction, hyperextension and internal rotation. The nailing is carried out by the extra articular technique.

None of the cases showed any sepsis and the wounds healed without discharge.

The methods suggested by Hey Groves and Watson Jones are followed. An incision is made on the lateral thigh in the subtrochanteric region. Guide wire is inserted and the nail driven in. The guide wire is then removed and anteroposterior and lateral x-rays are taken. With the position satisfactory, the incision is closed.

After closure, various movements of the hip joint are carried out by the surgeon and act as a guide to the thoroughness of the operative procedure. In bed the limb is supported with a soft pillow. Full leg exercises are begun twenty-four hours after operation. If the patient's condition permits he is allowed up in a chair on the fourth day bearing no weight on the leg. Patients are allowed up on crutches after the third week until the ninth week when they may bear weight on the injured leg. After that, the crutches are discarded as soon as the patient is able to get along without them.

Vascular necrosis of the head with associated osteoarthritis, absorption of the neck, and poor nail ing are complications which have occurred. An excellent result means painless movement without the slightest deformity or limp. No nails have been extracted except in the one case of absorption of the neck.

Forty-three case reports are abstracted. 16 roentgenograms are included. Sixteen and two-tenths per cent were subcapital fractures. 47.8 per cent were transcervical and basilar fractures; either intertrochanteric or pertrochanteric, occurred in 41.8 per cent. Fractures in females accounted for 83.2 per cent of the total. The end results were listed as good 72.3 per cent, fair 8.3 per cent and poor 8.3 per cent. 10.6 per cent of the patients died.

RICHARD J. BROWETT, JR., M.D.

Stanek, W. F.: Internal Derangements and Fractures Involving the Knee. Results of 156 Consecutive Arthroplasties Performed at a Station Hospital. *J. Bone Surg.* 1945 28-86

Injury to the knee, recent or old, constitutes one of the major problems of orthopedic surgery in the Army. Some surgeons assert that few soldiers operated upon for internal derangements return to full duty and it has been difficult to account for this. The author has therefore reviewed 156 cases of arthroplasty. These cases were divided into 6 classes in order that they might be more readily evaluated. The first 75 were originally tabulated in January, 1943 and include the patients operated upon from April through December, 1942 (Group 1). On the basis of the results obtained, certain changes were then made in the choice of cases to be subjected to operation. The second series of patients were operated on between January and October, 1943 (Group 2). The more interesting and unusual cases are briefly described in the original article.

In every case exploration of the anterior chamber of the knee was continued until the different pathological changes were located or a thorough examination was completed. Negative as well as positive findings were recorded on the operative sheets, a fact of considerable importance in the later evaluation of several of the cases. When a meniscus was removed as much of it was taken out as could be obtained through an anterior incision. When it was thought that the remaining portion might cause later difficulty a Henderson incision was used to obtain the remainder of the meniscus. In simple cases of injury to the meniscus, sheet wadding and muslin dressings were applied, quadriceps-setting exercises were started on the first postoperative day and the man was allowed to be up without crutches as soon as he could raise his leg unassisted from the bed. Frequently on the second or third postoperative day. No attempt was made to repair torn cruciate ligaments. Of the 156 cases, 103 showed injury only to the menisci, ligaments, or fat pad. Eighty-six torn medial menisci and 15 torn lateral menisci were removed. Two cases showed tearing of both menisci. Fifty-four bucket handle, 20 anterior, 10 posterior and 3 minimal tears (loose anterior attachments) are recorded.

Of this group of patients, 97 returned to some type of duty. In 24 cases disorders of the bone and articular cartilage were shown. Of 9 patients with osteochondritis dissecans, 8 are believed to be on duty while 11 with chondromalacia of the patella, 8 are probably still in service. Only 5 patients with severe arthritis were operated upon, and none of these are believed to be in the Army at present. Nine patients with recent or old fractures involving the patella, tibial spine, or tibial plateau were operated upon. Five of these have been discharged for disability. The last man of the group was discharged because of an ankle disability. Of the remaining patients in the series, those operated upon primarily for diagnosis have shown poor results. The

final diagnosis in most cases being psychoneurosis. Three unusual cases were found, and were described in detail

EMIL C. ROSENTHAL, M.D.

ORTHOPEDICS IN GENERAL

Thomas, A.: Anatomic and Physiological Considerations in the Alignment and Fitting of Amputation Protheses for the Lower Extremity *J Bone Surg* 1944, 26 645.

The efficiency and ease with which the amputee walks with his prosthesis depends upon the alignment and fit of the prosthesis, the site of amputation, the length and condition of the stump, muscle strength, mobility of the adjacent joints, and the mental attitude, skill, and aptitude of the amputee.

In the below-the-knee amputation, there is remarkably little disturbance of gait, because of a normally functioning quadriceps. The artificial foot gives adequate function through rubber cushions provided for by elastic pressure.

For amputations above the knee, walking depends mainly upon the success and control of the artificial knee joint. Elastic straps or inner springs are not essential to locomotion as the gait is similar to that of a person with a paralyzed quadriceps. The thigh is extended by the *gluteus maximus* and the absent calf muscles are substituted by placing the foot in slight plantar flexion. The stability of the knee joint is increased by placing of the axis of the knee joint posterior to the knee center.

The head and neck of the femur forms an angle of 125 degrees with the shaft, the longitudinal axis of which in the frontal plane is directed obliquely downward and inward. In the sagittal plane the femur curves slightly anteriorly. The hip joint of the prosthesis must be well anterior to the greater trochanter to coincide with the true axis in flexion and extension.

In order to compensate for the gliding mechanism of the artificial knee joint this is achieved by placing the knee bolt or side joint posterior to the knee center.

Function of the foot of the prosthesis is obtained by dorsal and plantar flexion only, and motion of the

metatarsophalangeal joints must be provided for and must correspond to the axis of the normal foot. It is important to provide toeing out of the artificial foot equal to the rotation of the normal foot in order to prevent rotation of the prosthesis on the stump which would cause abnormal friction and pressure. The opposite extremity must be matched closely in order to obtain as near a normal gait as possible.

The socket of the prosthesis for thigh amputations must be accurately shaped and fitted in order to bear weight comfortably and not interfere with the circulation of the stump. The socket is roughly triangular in shape and is constructed to bear weight on the ischial tuberosity, the lateral surface of the thigh, and greater trochanter. There is no stump weight bearing except in the case of amputations at or just above the knee.

For amputation below the knee, the socket must be so constructed that it will accurately fit the regular surface of the weight-bearing areas below the knee: the tibial condyles, the tibial tubercle, and the head of the fibula. The prosthesis must not cause any pressure in the popliteal space, as this would interfere with the circulation and cause edema. The socket should fit snugly and afford up-and-down motion. The posterior border of the socket should extend just as high as the anterior in order to avoid bulging of the soft tissues of the popliteal space. The side joints at the knee should be set posterior to the lateral knee center.

Suspension from the shoulders by means of a harness is still in common use, but pelvic suspension is becoming more popular as it affords a more normal and less fatiguing gait. It is attached to the prosthesis by means of a joint at the hip and should be well anterior to the greater trochanter to coincide with the true axis of the joint.

The lengths of the lower and upper extremity prostheses should closely approximate the normal leg, especially when pelvic suspension is used.

In short thigh stumps in aged or debilitated persons, the shoulder suspension is necessary and the prosthesis should be from $\frac{1}{4}$ to 1 inch shorter.

RUDOLPH S. REICH, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Rogers, L.: Carotid Ligation for Intracranial Aneurysm. *Brit. J. Surg.* 1944, 32: 309

A healthy man aged twenty two while driving a car had a sudden severe headache which necessitated his stopping and handing the steering wheel over to a passenger. For a fortnight previously he had noticed occasional twitching of his right eye. On waking on the morning after his attack of severe headache, he was unable to open the eye voluntarily. When the upper lid was forcibly raised the vision was found to be blurred. The condition gradually cleared up but five years later he began suffering from attacks of pain behind the right eye which caused a total disability.

He was a well built man with ptosis and a dilated inactive pupil on the right side. Movements of the eyeball were defective. The blood pressure was 210/100. X rays showed some calcification which was regarded as occurring in an aneurysm of the right internal carotid artery. The cerebrospinal fluid pressure was 180 mm. its protein content well below normal, and the Wasserman reaction negative. An electroencephalogram revealed nothing abnormal in any area either when resting or during overbreathing.

From April 5 until April 28, 1944, digital compression of the right common carotid artery was performed, at first for five minutes, later as long as twenty minutes each day. On April 29 the right common carotid artery was exposed under novocain infiltration and temporarily occluded by a piece of tape surrounded by four waxed silken threads tied over it in a half hitch which was held in the beak of a curved hemostat. The systolic blood pressure was now 190 and remained so throughout the operation. Dynamometer readings were taken every three minutes from both hands over a period of an hour and a half and at intervals during this time electroencephalograms were also obtained and reported upon as follows:

During occlusion of the right common carotid the right hemisphere showed slightly more prominent normal rhythms than the left. These were never outside the physiological range and towards the end of the period (1 hour 20 minutes after occlusion) the asymmetry was less marked than at first. These observations suggest that the carotid occlusion did not result in any significant arterial anoxia.

As neither the electroencephalogram nor the dynamometer readings gave any indication of serious impairment of cerebral function the common carotid artery was secured in two places by silk ligatures and divided between these. A striking phenomenon was the extent of the retraction of the divided ends of the vessel, so that they were separated by at least an inch.

The pain left the ptosis lessened, and the movements of the eyeball improved and with them the vision. There has been no hemiplegia. An electroencephalogram three weeks after operation showed all rhythms within normal frequency which confirmed the belief that the carotid occlusion had no significant effect on cortical function.

The author was not able to find any previous report of electroencephalographic studies made during carotid occlusion. In his case these showed that during temporary occlusion of the common carotid lasting almost an hour and a half no significant change in cerebral function occurred. This was supported by measurements of the strength of the hand grip made during the same interval. In such cases it cannot be said however, that a delayed hemiplegia will not follow the occlusion. An example of this occurring some twenty hours after ligation of the internal carotid has been reported by the writer in a case of fatulous carotico-cavernous aneurysm. In order, therefore to lessen the possibility of such a delayed complication it was decided to ligate the common rather than the internal carotid and thereby leave a trickle of blood through the aneurysm as in the classical operation for popliteal aneurysm performed by John Hunter on the femoral artery with the object of promoting the formation of protective laminated clots. The danger of delayed hemiplegia would appear to be greater from primary ligation of the internal carotid because having no branches this vessel when tied forms a long test tube full of blood which if it clots may by extending upward obstruct the terminal branches and thereby seriously interfere with cerebral function.

The degree of longitudinal tension in the carotid artery as evidenced by the extent of the retraction when this artery is divided (commented upon in the case recorded here) suggests that this division is advisable since it reduces the local pumping action which may liberate clot from the site of a ligature applied in continuity and thus give rise to delayed embolism.

Since reporting this case the author has operated upon 2 others in which electroencephalograms were equally helpful. In each of these as the tracing following temporary occlusion showed no significant change the common carotid was tied and divided without incident.

JOSEPH K. NARAY, M.D.

Glasser, S. T. Ligation of the Femoral Vein for Chronic Occlusive Arterial Disease: A Review of 113 Ligations. *Arch. Surg.* 1945 50: 56.

During the year of 1941 the author collaborated in the study of 20 cases of chronic occlusive arterial disease of the lower extremities in which ligation of the femoral vein was employed as the method of treatment. The encouraging results of that study demanded further evaluation of this procedure. The

present report includes 118 ligations of the femoral vein in 110 patients. The author notes that the results are far from spectacular but the value of this procedure, as judged from his experience, definitely places it in the armamentarium for the treatment of chronic occlusive arterial disease.

A discussion then follows relative to those surgical procedures which are of therapeutic value in cases of occlusive arterial disease. For the most part, these procedures actually attempt to bring about the ultimate development of collateral vessels, since this is the only means by which improvement can occur. An extensive discussion is presented of experimental and clinical reports of various workers who have studied the effects of ligation of a major vein such as the femoral.

Ligation of the femoral vein proximal to the saphenofemoral junction causes temporary edema. A small degree of this swelling may be due partly to reflex vasospasm and, when recognized, may be amenable to lumbar ganglion with procaine hydrochloride. In the experience of the author ligation immediately distal to the junction of the vena profunda with the superficial femoral vein is free from subsequent edema.

The experience with this series of cases is that there has been complete absence of pulmonary complication following ligation of the femoral veins, especially when amputation was performed subsequently.

The relief of pain following ligation of the femoral vein in the majority of cases was noted and mentioned in the preliminary report of the author. Relief of pain results not only from the increased collateral circulation with its attendant increased oxygenation of the tissues. Division of the femoral vein must necessarily include partial interruption of the sympathetic pathways and this also is a probable factor in the relief of pain.

The author discusses his technique for performing this ligation and presents an analysis of the cases which are reported. In his opinion, ligation of the femoral vein is definitely indicated for prophylaxis in chronic obstructive arterial disease—before such lesions as gangrene, ulceration, and infection present themselves. Ligation of the femoral vein is not associated with morbidity or mortality. Relief of pain was obtained in the majority of the cases. The prevention of subsequent pulmonary embolism following amputation is definite.

In order to determine indications for the procedure and a proper selection of cases, ligation of the femoral vein was performed on all patients with chronic obstructive arterial disease who consented to the operation. As a result, this series included patients whose condition was unfavorable or hopeless in view of such complications as spreading gangrene and sepsis. However, the ligation of the femoral vein was of definite value in the prevention of gangrene and the alleviation of pain. An increased collateral circulation was evidenced by increased bleeding, which was noted at amputation following ligation of

the femoral vein, and also by means of arteriography. In 6 of the patients the pulses became palpable post-operatively.
HARRIS F. THURGOOD, M.D.

Glus, J. A., McGovern, J. D., and McMurray, W. R., Jr.: Portal Vein Thrombosis following Removal of Ruptured Spleen. *Ann. Surg.* 94, 15, 100.

Thrombosis of the splenic and portal veins is a not uncommon, though often an unrecognized complication following splenectomy. It would appear that this complication is most likely to occur in splenic anemia. A case is reported in which thrombosis of the portal vein followed splenectomy for traumatic rupture of the spleen. The patient was a white male, age thirty-five who fell and struck his left costal margin against a rail five hours prior to his admission to the hospital. The past history revealed that he had experienced an attack of acute abdominal pain which had been diagnosed as gall-bladder trouble six years previously. Operation was carried out several hours after admission and the spleen, which had two deep lacerations on its convex surface, was removed. Postoperatively the temperature showed slight daily elevations from 1 to 2 degrees above normal until the patient was discharged from the hospital on the seventeenth day. While at home he had recurring attacks of pain localized to the left upper abdomen immediately after eating. Later the pain shifted to the right upper quadrant and slight jaundice developed. He was treated conservatively until twelve days after the onset of pain in the right upper quadrant, at which time operation was undertaken for subsiding acute cholecystitis and cholelithiasis. The gall bladder was edematous and friable, it contained stones and was surrounded by adhesions. Considerable bleeding which was difficult to control was encountered. The gall bladder was removed and a pack was left in place to control hemorrhage. The patient's condition was poor and he expired four hours later. Postmortem examination revealed a thrombus in the portal vein extending into both the right and left branches, and a thrombus in the splenic vein.

It is presumed that the thrombus formed at the point of ligation of the splenic vein became partly dislodged, entered the left main branch of the portal vein, and produced an occlusion. Retrograde propagation of a thrombus could then follow the clot finally encroaching upon the ostium of the cystic vein with obstruction to the venous return from the gall bladder. The resulting vascular stasis in this organ caused the clinical picture of acute cholecystitis. Previous disease of the biliary tract may have been a contributing factor. Death was caused by uncontrollable hemorrhage and shock during the cholecystectomy. The increased portal venous pressure and friability of the tissues made complete hemostasis unobtainable.

It is probably a good rule to delay all elective intraperitoneal operative procedures following splenectomy until adequate circulatory readjustments

have been made. Absence of the spleen may be a factor in the inadequate response of the patient to shock and hemorrhage. Prolonged fever, abdominal pain, increased leucocyte count, and increased platelets and erythrocyte sedimentation rate following splenectomy should suggest splenic and portal vein thrombosis.

JOHN L. LINDBQUIST, M.D.

BLOOD TRANSFUSION

Popper H., Volk, B. W. Meyer K. A. Kozoll, D. D. and Steigmann F.: Evaluation of Gelatin and Pectin Solutions as Substitutes for Plasma in the Treatment of Shock: Histological Changes Produced in Human Being. *Arch. Surg.* 1945, 50: 34.

Experiences with the administration of gelatin and pectin solutions, which were used as substitutes for plasma in the treatment of shock, to a series of 317 patients in shock and not in shock were compared. The two solutions produce an equal degree of hemodilution, which levels off with administration of higher doses of both solutions. The leveling off is more pronounced in patients with anemia and hypoproteinemia. The hypothesis is suggested that the hemodilution is started by the macromolecular solution, but is maintained by other substances, possibly labile plasma proteins.

Gelatin and pectin solutions produce an equal rise in the sedimentation rate, which is considered an index of hematological changes. The significant difference between the two solutions lies in the fact that gelatin produces less change in the tissues whereas, after administration of amounts of pectin in excess of those used for patients in shock, splenomegaly and deposition of a peculiar material in various organs may be observed. This material is selectively stained by ruthenium red, a dye used for staining pectin. It is found in phagocytic cells, capillaries, tissue spaces, and infiltrating reticulum fibers in the spleen, kidneys, liver, and lungs. It resembles deposits of amyloid, and causes a reaction of the reticuloendothelial cells. A similar picture was produced in animals by the administration of large amounts of pectin. The clinical significance of these changes is unknown.

Since the beneficial effects of gelatin and pectin appear equal, gelatin appears preferable to pectin in the form used on the basis of the changes in the tissues.

SAMUEL KAMIN, M.D.

RETICULOENDOTHELIAL SYSTEM

Mazel, M. S.: Traumatic Rupture of the Spleen. *J. Pediat.*, S. Louis, 1945 26: 82.

An analysis of 3 cases of traumatic rupture of the spleen in children revealed a history of a fall or injury to the left upper quadrant of the abdomen or lower chest with signs of internal hemorrhage and abdominal rigidity and without external signs of injury to the chest or abdomen.

The reduction of the red blood-cell count and of the percentage of hemoglobin was not pronounced a short period after the occurrence of the splenic rupture.

Roentgen examination did not show fracture of the ribs, due to the resilience of the ribs in young children.

Shock and internal hemorrhage were treated by transfusions of whole blood before and after operation. In 1 child a single rupture of the spleen was approximated with interrupted mattress sutures and continuous sutures of the capsule. Multiple injuries of the spleen necessitated splenectomy in other children.

ERNEST E. ARNHEIM, M.D.

O'Neill J. F. and Rousseau J. P.: Roentgenological Examination of the Abdomen as an Aid in the Early Diagnosis of Splenic Injury. *Ann. Surg.* 1945 122: 111.

A valuable roentgenographic diagnostic sign of splenic injury following abdominal trauma is presented. It is attributed to Solis-Cohen and Levine and is substantiated by the authors in the present article.

In splenic hemorrhage of traumatic origin the shadow of the spleen is absent and the stomach is dilated with serration of its greater curvature. The cause of the serration remains unproved. These changes are not encountered in splenomegaly or after splenectomy.

The authors present 2 verified cases of splenic injury, one with massive hemorrhage and one with moderate bleeding, which are compared with an extensive injury of the left kidney, in order to evaluate the reliability of the roentgen findings.

Conclusions from this article corroborate the presence of a gas-containing stomach with a serrated greater curvature (as demonstrated on a plain abdominal film) in either a small or large hemorrhage of the spleen.

R. A. BERGER, M.D.

SURGICAL TECHNIQUE

WAR SURGERY

Tunbridge, R. E.: Cause, Effect and Treatment of Air Blast Injuries. *War Med.*, Chic., 1945, 7: 3.

The increased use of high explosives in modern warfare has been accompanied by recorded cases of injury attributed to the effects of air blast. In a particular incident it may prove difficult to obtain an accurate history of the event, and without this it is often impossible to ascertain the exact cause of the injury as different factors may produce similar pathological changes.

The pathological findings in cases of blast injury are (a) hemorrhage resulting from rupture of the capillaries and smaller vessels, more especially those of the ear, chest, and abdomen (b) rupture of organs, pulmonary alveoli, abdominal viscera, and the aorta and (c) cerebral damage.

The finding of bilateral pulmonary hemorrhages is not, however pathognomonic of blast injury and has been described in compression asphyxia, asphyxia, carbon monoxide poisoning, and in pulmonary fat embolism.

Injuries due to air blast are best subdivided into 3 groups: mild, moderate, and severe.

The mild injuries are readily overlooked, as the symptoms are not severe. There may be tightness of the chest, pain in the wall under the sternum or of the chest, irritable and paroxysmal cough, and slight deafness. In fact, the symptoms may appear to be so out of keeping with the general well-being of the patient as to lead to their being considered psychosomatic manifestations. The later differential diagnosis provides the only clinical problem. Treatment consists of rest, mild sedation, and reassurance. Recovery is complete within fourteen days.

The moderate injuries are frequently accompanied by other injuries, and the visual evidence of wounds often leads to the overlooking of injuries due to air blast. In the author's opinion, associated surgical conditions should be treated on their merits, and operation or blood transfusion should not be withheld on account of the presence of blast injuries. The prognosis of severe wounds associated with blast injury is worse than that of wounds not so complicated, but treatment, viz., rest and oxygen, is unaffected. If pyrexia develops after a period of from thirty-six to forty-eight hours, chemotherapy should be begun because of the likelihood of infection of the hemorrhagic areas.

The severe injuries present no problem because the patient rapidly loses consciousness and usually dies within twelve hours. Temporary relief is sometimes afforded by venesection, but morphine is the chief therapeutic weapon.

Air blast is an undoubted cause of death and is a complicating factor when associated with other injuries. The sequelae from air blast are few: deafness

and postconcussive syndromes. The pulmonary lesions in persons with nonfatal injury unless secondarily infected, resolve completely. The minor degrees of injury are often overlooked, and the patients are incorrectly reported as suffering from psychosomatic disease.

JOHN E. KIRKPATRICK, M.D.

Berk, J. E. and Frediani, A. W.: The Peptic Ulcer Problem in the Army. *Gastroenterology* 1944, 4: 415.

Peptic ulcer has proved to be surprisingly prevalent among military personnel and is responsible for the loss of many manpower hours. Of 841 enlisted personnel admitted to the Gastrointestinal Section of the Tilton General Hospital, Fort Dix, New Jersey 340 or 40.4 per cent, of the patients proved to have peptic ulcer. This figure does not indicate the incidence of peptic ulcer in the armed forces at large, since this installation receives a selected group of cases. Approximately 74 per cent of the inductees in this series presented symptoms indicating the existence of ulcer prior to induction. The average length of service by the inductees prior to the first hospitalization in the Army averaged only seven and one half months. The average age of these patients was twenty-nine and one half years. In 309 cases with accurate records, 310 ulcers were found, of which 303 were duodenal, 6 gastric, and 1 jejunal. Duodenal ulcer therefore, constituted 98.7 per cent of all the ulcers, with a ratio of duodenal to gastric ulcer of 50 to 1. Atypical ulcer histories were obtained particularly from younger persons whose symptoms were of short duration. It was necessary to resort to antacids for the relief of pain in only 18 per cent of the patients. Psychosomatic factors are outstanding in military personnel with ulcers. The influence of anxiety, tension, and emotional unrest is unmistakable. There is a greater tendency toward lower levels of gastric acidity in young soldiers with ulcer than in comparable groups of older patients. This suggests that with repeated recurrences and with chronicity the gastric acidity in ulcer patients rises.

Complicating features, either in the past history or at the time of admission were hemorrhage in 17.7 per cent of 225 cases in this series, perforation in 7.6 per cent and pyloric obstruction in 3.1 per cent. It was found necessary to operate on only 3 of 340 men with peptic ulcer: on 1 because of an acute perforation, on 1 because of posterior penetration with intractable pain, and on the third because of a large gastric ulcer which failed to heal completely on a medical regimen. The authors believe that the promiscuous employment of gastric resection or other types of operative procedure in military personnel with uncomplicated ulcer merely in the hope that it will render them fit for duty is unwise.

The prevalence of peptic ulcer in the Army is largely a reflection of the unsuspected frequency of the disorder in the adult population. Although they cannot prove it the authors believe that active military service and all it connotes is influential in the causation of ulcer. They are sure that psychogenic factors connected with warfare have an influence on the clinical behavior of soldiers with ulcer. Many soldiers with ulcer tend either consciously or unconsciously to exploit their defect. In general soldiers with peptic ulcer fare poorly in the Army. For these reasons, it is the policy to separate from the service all soldiers with ulcer unless their skill, capabilities or experience outweigh the risk of their retention in the service. JOHN L. LINGGERT, M.D.

Oldfield, M. C.: Some Experience of Reparative Surgery in the Middle East. *Brit. J. Surg.* 1944, 32: 237

A preliminary review of the 1,300 cases treated by a maxillofacial unit in the Middle East during a period of two years is presented and a short survey of the methods used for the treatment of the commoner types of injury is given. Some impressions of the treatment of 195 cases of severe burns are given. The back of the trunk was involved in all of the 4 patients who died from the effects of burns. A short description is given of some of the complications that have occurred. The importance of air evacuation, burn centers, external pin fixation for certain facial fractures and rigid dressing technique is emphasized. LOUIS T. BYARS, M.D.

Bosworth, B. M.: Treatment of Fractures in the Combat Area. *Am. J. Surg.* 1945, 67: 342

Fracture at the front presents peculiar problems. Early and safe transportation is a prime consideration. Treatment must be designed for the comfort of the patient and the convenience of the medical personnel. Multiple injuries complicate the treatment. Treatment which is considered the best for fractures must often be altered. Lack of equipment is a very real factor in combat areas and those who are ingenious at improvisations will have the most successful results.

A major complication of war fractures of the extremities which the author encountered occasionally was tamponade of the circulation due to an unsuspected hemorrhage beneath the deep fascia. In many cases the bone or bones were terribly shattered and quite often there was a massive loss of soft tissues as well. All casts applied in this area were padded and then they were split or bivalved throughout their length. The separation must go through all of the dressings and bandages right down to the skin itself. The Tobruk splint for fractures of the lower extremities is described and illustrated but the author prefers a well applied spica cast.

Nerve injuries are common and are a serious complication for war fractures. The possibility of their presence must be kept in mind when the patient is prepared for primary surgery. In the combat area

open reduction of simple fractures is not permitted but the treatment of compound fractures is left pretty much up to the individual surgeon. When some form of skeletal fixation was imperative the author preferred plates of vitallium or stainless steel to the Roger Anderson and similar pin transfixion methods as he considered them to be much quicker surer and simpler. Sodium pentothal was given frequently by the intravenous method in the treatment of major fractures in the combat area.

Longland, C. F. and Kessel, L.: Surgery in an Airborne Division. *Brit. J. Surg.* 1944, 32: 275

This communication gives an account of the present surgical service in a British Airborne Division and the history of its development. The general difficulties of such a service are that asepsis and mud may have to be roommates, clean areas must be guarded from the inroads of unfavorable surroundings, slender resources must be carefully husbanded, technique must be kept simple while principles are obeyed, nursing is beset with difficulties and real comfort is almost out of reach. In addition there are problems peculiar to the service.

1. Though long range mobility is one of their characteristics, once on the ground airborne troops are relatively immobile. This favors the use of operating centers which are necessarily static affairs once established.

2. Because of the lack of motor transport and the limited loads which aircraft can carry the amount of equipment these troops command is strictly limited. This affects the choice and packing of equipment. Other factors beside total weight must be considered. Loads must be designed so that they can be carried by one man across rough country on foot and these loads must fit into the containers in which equipment is carried by the aircraft. There must also be sufficient duplication of essential items to minimize the effects of loss of some loads.

3. In their most typical type of operation airborne troops fight inside enemy territory and have no rearward ground communications. This means that evacuation of casualties to rearward hospitals is impossible for some time and surgery must be provided by the medical unit concerned. Adequate nursing is essential to secure good results from the surgery and until the airborne troops join up with the ground troops the wounded accumulate in the dressing station. It may be impossible to place the operating center out of range of even the lighter weapons, but this disadvantage can be reduced if the site is carefully chosen.

Careful planning of the entire airborne operation and the co-ordination of the surgical team in the plan is essential. The surgical teams generally consist of a surgeon and five orderlies with another medical or dental officer attached as anesthetist, and as a rule two such teams work in conjunction. The teams require the help of men assigned to other duties in the main dressing station in the handling

of their equipment. After the landing the medical personnel assist those injured in the landing, and the surgical teams take no special part in dealing with these casualties. By the time the operating center is ready to function the teams will have done a considerable amount of physical work with loss of much sleep so that if conditions permit, short initial shifts are arranged for the teams.

The aim of the surgical methods is to provide the full recognized forward surgical treatment for all types of casualties, such surgery being directed toward making the patient safe and comfortable for the journey to base hospitals and giving the wounded tissues the best chance of rapid and complete healing. Such work differs little from that of the ground field surgical units. The delay in evacuations modifies the treatment to be adopted in a few special types of wounds ordinarily best sent back to specialist units, notably the penetrating head injury. Jaconet is used instead of linen and the "two-bench circuit" method of providing instrument sets for successive cases has proved satisfactory. Lighting is provided by paraffin pressure lamps with incandescent mantles, by electric head lamps, and by accumulator-operated spot lamps on stands. Penitohal-sodium anesthesia is most suitable for air borne work because of its facility of administration without bulky equipment. Ether is dangerous in the presence of naked flames and has been abandoned in favor of chloroform, which has the further advantage of being less bulky. Plaster of Paris, because of its weight and bulk, is not ideal for splinting, and it is difficult to supply sufficient quantities of this essential material. The casts used are based on three standard patterns for each limb: these are the "box" plaster, the full arm plaster and a roller splint to hold wrist, hand and digits in the position of function for the upper limb; the simplified "Tobruk" plaster for the full leg plaster and the lower leg plaster for the lower limb. Transfusion fluids are also limited because of weight and bulk. Facilities for postoperative nursing, particularly for abdominal cases, are limited. In spite of all the difficulties involved it is now possible to give isolated airborne troops the benefit of early wound surgery.

JOHN L. LINDQUIST M.D.

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Cayford, E. H., and Pretty H. G.: Refrigeration Anesthesia and Evaluation of Amputation Sites by Arteriogram. *Ann. Surg.* 1945 21 57

Cayford and Pretty discuss the use of lowered temperatures in limb amputations of 22 patients. In nearly every instance the patient was a grave operative risk and some of the patients could not have been treated surgically were it not for this method of anesthesia. There were 4 deaths, 3 of which were due to gas gangrene.

Refrigeration anesthesia cools and numbs the tissue cells en masse. It is, therefore, a general tissue

depressant without any particular selective action on the nerve trunks. Refrigeration produces first of all, a vasoconstriction, and later a vasodilatation, this reduces edema and minimizes transudation of tissue fluids which renders the tissues firm. Shortly after refrigeration commences there is a mild analgesia over the once painful extremity. The patient, relieved of his agonizing pain may now enjoy a substantial meal before going to the operating room, or immediately afterward. There is no shock whatever to the procedure, as determined by the ordinary signs and symptoms or by the Scudder estimation. There is no real necessity of a sedative, although in many nervous people a sedative is probably advisable. The anesthesia is adequate and will last about one hour; this allows the surgeon to carry out any type of amputation procedure desired. The sawing of the bone sometimes disturbs the patient, but he will generally admit there is no pain. Severing of the large nerve trunks is quite painless but the nerves cannot be pulled down for higher section without some pain. To obviate this discomfort, it is simple to separate the muscle fibers upward an inch or so; the nerve can then be cut off above the line of amputation. Novocaine and alcohol, or novocaine alone can be injected into the nerve to avoid the painful neuroma later.

The tourniquet was dispensed with in 18 of the 22 cases, and the early and uneventful healing of the stump wounds is attributed to this fact.

A modification of the Allen technique was employed. Usually a mild sedative is given before immersion of the limb in the ice. The temperature at the skin surface is reduced to and maintained at 5° C. If a tourniquet is to be used it is applied one hour after refrigeration commences. During refrigeration the patient may be given coffee or whisky, or a regular meal. Without the tourniquet the refrigeration required is about one hour more at each site, but it may go on indefinitely without harm.

The amputation site is undoubtedly going farther down the limb. This is attributed not only to refrigeration without the tourniquet and to the improved metabolic condition of the tissues, but also to the use of arteriograms. Arteriography is a comparatively new field but it will undoubtedly offer a great contribution toward the establishment of the proper site for amputation and go hand in hand with refrigeration in the conservation of limb length and lives. It makes visible the collateral circulation which is not determined by means of skin temperatures or oscilometric readings. Furthermore, it determines the exact patency of the main vessel at a higher level than is anticipated by any other tests and eliminates any element of doubt regarding the site of amputation.

STEPHEN A. ZILMAN, M.D.

Pritchard, J. E.: The Biopsy as an Accurate Guide to the Decision of Early Skin Grafting. *Ann. Surg.* 1945 1 64.

When a burn wound requires skin grafting it is desirable that it be done as early as possible. Therefore, it is important to have some means of determin-

ing whether the wound can be expected to heal spontaneously and satisfactorily or whether this cannot be expected and skin grafting is required.

The healing of a burn depends upon the viable epithelium in the burned area which is available for re-epithermization. The epidermis at the margins of the wound the surface epithelium that has escaped destruction the hair follicles, the sebaceous glands, and the sweat glands supply the material for re-epithermization. For satisfactory spontaneous healing, there is required at least a sufficient number of hair follicles and sweat glands therefore hair follicles which lie at a higher level than the sweat glands except in hairy parts, must be spared in sufficient numbers if spontaneous satisfactory healing is to be obtained. If destruction should involve most or all of the hair follicles but spare the sweat glands which lie at a deeper level spontaneous re-epithermization may still be expected but the process will be slow and it will be attended by the formation of granulation tissue which organizes into fibrous tissue, so that the remains of the viable deep layer of the fibro-elastic corium becomes overlaid by a thick layer of scar tissue covered by hyperkeratotic epidermis—an unsatisfactory result. If the destruction extends deep enough to involve the sweat glands, there will be no source of re-epithermization other than that at the margins of the wound, and this, in all but very small burned areas, is inadequate.

At the time of removal of the first dressing all questionable cases are subjected to biopsy in order to determine the expectancy of the healing of the wound. It soon became the practice to prepare rapid frozen sections of this tissue in the operating room and upon the report of the pathologist, the decision to graft or not to graft is made at once. In the biopsies the finding of destruction of the skin to a level below the hair follicles indicates that satisfactory spontaneous healing cannot be expected and that skin grafting is required.

LOUIS T. BYARS, M.D.

Jenney J. A.: Modification of the Plasma Fixation Method (Sano) of Skin Grafting by the Use of Bobbinet and a Mirror Attachment *Am J Surg* 1945 67 3

Among the difficulties encountered in the use of Padgett dermatome grafts are the removal of the graft from the dermatome, sticking of its cemented surface to adjacent surfaces, holding the graft on the recipient area, contraction of the graft, mutilation of thin grafts when they are separated from the dermatome, and interference of vision of the operator by the drum during the cutting of the graft. To avoid these difficulties, a method is proposed which involves the use of bobbinet on the drum of the dermatome and a mirror attached to the cutting arm.

A piece of washed cotton bobbinet is cut about 1 inch larger in all directions than the area of the drum of the Padgett dermatome. The drum is painted with rubber cement, allowed to dry, and the piece of bobbinet is then rolled onto the drum. Another coat

Fig. Reflection of the bobbinet and graft in the mirror (Courtesy of American Journal of Surgery)

of cement which is sufficient to saturate the bobbinet thoroughly is applied and the ends and sides of the bobbinet are pasted down. The drum may then be autoclaved or sterilized in a steam sterilizer. Adhesive qualities of the sterilized drum are tested with the surgeon's glove and if the drum is a little dry it is repainted with a thin solution of the cement.

A pattern is then made of the recipient area and it is marked out on the donor area with dye. The skin is then superficially incised with a scalpel along the line of the borders of the graft. The area within the incised line is cleaned with ether and painted with rubber cement; the area outside the incised line is powdered with talcum or sulfazaline to prevent adhesion between the rubber on the dermatome and the skin. The skin around the recipient wound is painted with rubber cement. The mirror is then attached to the instrument and the graft is cut in the usual manner (Fig. 1). The ends of the bobbinet are loosened and by gentle traction the fabric with the adherent skin is peeled off the drum. Towel is applied to the rubberized surface which was next to the drum in order to avoid adhesion to gloves.

Graft and recipient areas are treated according to the plasma fixation technique of Sano. The graft is then fitted accurately to its place in the wound being applied at one end and rolled down and the margins of the rubberized fabric are pressed into the prepared skin to which they adhere. Sutures are

placed, if needed and a pressure dressing is applied. Good results have been obtained on even surfaces with no dressings at all over the fabric, but in such cases bleb formation is more common. When the grafts have become well vascularized the bobbinet may be removed. By saturating the deeper layers of the dressing with either or cement solvent, the bobbinet can be picked off easily. In covering large granulating wounds the bobbinet held grafts may be cut into strips which are laid across the prepared base and pasted to the skin adjacent to the wounds.

The advantages of the bobbinet are that it facilitates handling of the grafts, thin grafts are not mutilated pattern grafts may be cut accurately contraction of the grafts is eliminated the grafts can be molded over forms to line cavities as in buccal ulcers, and a minimum of suturing of grafts is needed.

The mirrors are cut from large metal mirrors such as are used by photographers. They measure 7 by 3½ inches and are fixed by posts to the cutting arms of the dermatome or to the knife clip. The mirror simplifies the cutting of the graft by adding illumination of the graft, and by permitting the operator to work in a comfortable position and to view the operation of the knife at all times.

JOSEPH J. McDONALD, M.D.

Roberts, W. M. and Schaubel, H. J.: Vaseline Gauze Contact Fixation of Split Thickness (Padgett) Skin Grafts. *Am. J. Surg.* 94:5 67, 6.

To overcome the problem of fixation of split thickness grafts to the recipient area, and particularly to avoid the tedious job of suturing the grafts, the authors have sought new techniques. Fixation with strips of adhesive tape was tried and although this method was more rapid than suturing and gave a satisfactory percentage of take it was found to be time-consuming. Furthermore, the edges of the skin graft showed a tendency to curl under and the graft would retract to some degree because of its inherent elasticity.

More recently a fixation method by means of contact of the skin with vaseline gauze has been employed. Sterile vaseline gauze strips about an inch wider and longer than the graft to be taken are made up. After the graft is cut with the Padgett dermatome hemostats are clipped onto the skin graft borders, and with these as handles, the graft is placed on the vaseline, the stratum corneum layer being in contact with the vaseline gauze. Sulfathiazole powder is sprinkled on the raw surface. The hemostats are then removed from one end of the graft and a picture roller guided across the graft under constant firm pressure, removes the remaining hemostats as the roller passes them. The graft now adheres firmly to the vaseline gauze with no tendency of the skin edges to curl. In the absence of a picture roller the graft can be pressed onto the vaseline gauze with Kelly clamps. The graft is then transferred to the recipient area, and through the transparent vaseline gauze it is a simple matter to place the graft in exactly the desired position. The overlapping vaseline-

gauze borders adhere nicely to the healthy skin borders surrounding the wound and no sutures are used. A pressure dressing is then applied and held in place by a stockinette bandage. For large wounds, several drum grafts may be placed side by side on large sheets of vaseline gauze, and applied with the same technique. If small pattern grafts are needed they can be easily cut to the desired size when held by the vaseline gauze.

A series of 80 patients were treated with Padgett dermatome grafts. On 43 patients, the grafts were held in place by means of adhesive strips, and on 37 patients the grafts were held entirely by means of silk sutures. The percentage of take in both groups was satisfactory. In 12 patients, the vaseline-gauze-contact method was used with an unusually high percentage of take, i.e. above 90 per cent in all cases.

The importance of preoperative and postoperative care to maintain the patient in good general physical condition is stressed. Transfusions are recommended whenever the hemoglobin level is below 86 per cent. When donor areas are limited the authors take split thickness grafts from the same donor area several times, allowing a suitable interval of time for healing. On occasion grafts have been taken from previously grafted areas with rapid healing of both the freshly denuded area and the graft.

JOSEPH J. McDONALD, M.D.

Zintel, H. A.: Resplitting Split Thickness Grafts with the Dermatomy. A Method for Increasing the Yield of Limited Donor Sites. *Ann. Surg.* 94:5 2.

In order to cover large skin defects rapidly with split thickness grafts in patients with limited donor areas a method of resplitting Padgett skin grafts into two or three layers is presented.

The donor skin is cut as thickly as possible without interfering with regeneration of the epithelium (in adults from 0.030 to 0.038 of an inch, in children from 0.012 to 0.018 of an inch). With the graft still adherent to the dermatome drum the knife is adjusted to one half the original distance from the drum. By passing over the first quarter of an inch of skin before the blade is adjusted, rolling or separation of the leading edge of the skin is prevented then by repetition of the cutting process the graft may be split into two layers. At times it is possible to cut a graft into three layers. Thus, the skin from a given donor area can be used to cover an area from two to three times as large.

The take of the inner layer of a "split-split" thickness graft is quite similar to the healing of a Padgett donor area, ten or twelve days being required for it to become covered by delicate epithelium. To avoid injury of the delicate new epithelial layer the primary dressing is not changed until the tenth day and the layer of gauze in contact with the graft may be left until the fifteenth or sixteenth day. In 5 of 6 patients in which the "split-split" thickness grafts have been tried from 90 to 100 per cent of

the grafts remained viable. In one case in which an ordinary Padgett split thickness graft was unsuccessful, split-split thickness grafts were also unsuccessful.

JOSEPH J. McDONALD, M.D.

Clute, H. M. Kenney F. R. and Hamilton, B. E.: The Management of Postoperative Complications in Thyroid Surgery *Surgery* 1944, 16 739.

Oxygen is given to many patients after thyroid surgery for some hours after operation especially if they are toxic. Glucose in distilled water or in saline solution is given intravenously. Lugol's solution may be added to the intravenous solution. Nausea and vomiting which are usually due to the preoperative and postoperative medication and the anesthetic are readily managed by replacing intravenously the fluids and salts that have been lost. Nausea and vomiting are not infrequently related to the use of morphine and cease when this drug is discontinued.

Postoperative hemorrhage is a rare occurrence but when it does occur it may develop at catastrophic speed. When such a hemorrhage occurs the wound must be widely opened in the patient's room. Large gauze packs should then be placed over the wound and the patient returned to the operating room. The bleeding vessel should then be ligated. Severe hemorrhage is usually from the superior or inferior thyroid artery and if no bleeding point can be found then both vessels should be ligated.

The authors remove all skin sutures twenty four hours after operation. This greatly improves the scars. No wounds have separated following this procedure. Should serum collect under the skin it is aspirated. Should brawny edema of the skin flaps develop it should clear up in a few days. Hot poultices or ice bags may be applied for comfort.

A rare complication is an infection extending into the superior mediastinum. This is most apt to occur after the removal of a substernal goiter. It should be suspected if there is a rising pulse and a moderate fever the pulse being proportionately much higher than the fever when there is toxicity of the patient. A ray examination should show typical widening of the mediastinum. Immediate reoperation is indicated to cut the prethyroid muscles transversely and drain the mediastinum.

Tracheitis may be relieved by steam inhalations. Marked stridor, cough, trouble in swallowing and even regurgitation of liquids through the mouth or nose are most unusual. They are probably due to injury to (1) the superior or inferior laryngeal nerve, (2) the fine muscles of the neck, or (3) an actual spasm of the tracheal muscles. Temporary relief may be gained by the use of oxygen or oxygen and helium. If marked swelling is present, the wound must be widely opened and preparations made for tracheotomy. The tendency in the presence of marked stridor is to delay tracheotomy too long.

Injury to one recurrent laryngeal nerve may occur with no accompanying symptoms. After operation the patient's voice may be affected particularly

as to tone and volume, this may be a transient or permanent change. No special treatment is indicated. Bilateral injury to this nerve is most serious and may be fatal. Should this complication occur examination of the larynx makes the diagnosis readily apparent. The seriousness of this complication may not become apparent until the patient is up and about, when with increased exercise breathing becomes more difficult and a great increase in stridor occurs. In such cases eight or ten months should elapse before any radical treatment is instituted as one cord may regain its motility. Submucous resection of the cords or the transplantation of the omohyoid muscle to the base of one arytenoid cartilage and reconstruction of the larynx should be considered.

Postoperative thyroid storms are far less frequent and much less severe than in the past. In serious postoperative thyroid cases the patient is placed in an oxygen tent at once and oxygen continued for hours or days as indicated. Intravenous instillations of 5 per cent glucose in physiological saline solution alternated with 5 per cent glucose in distilled water are given so that the urinary output is brought to 1000 or 1500 cc. per day. Ten drops of Lugol's solution are added to each intravenous infusion until 30 drops per twenty four hours are given.

Auricular fibrillation is no cause for alarm. The authors use digitalis to control the heart rate in these cases. Recently they have used lanatoside C intravenously. Tetany is treated by giving calcium lactate intravenously. EARL O. LATIMER, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Patrick, W.: Wound Treatment by Delayed Suture *Brit. M. J.*, 1944, 2 788.

The initial operative treatment of soft tissue wounds in conjunction with sulfonamide or penicillin therapy and early secondary suture along with the technique of penicillin administration are intended to prevent or minimize infection as well as to encourage early healing. In spite of these efforts in the forward areas, very many granulating wounds, some of considerable size, still reach the base hospitals with infection well established. Some time has usually elapsed since the injury, and these wounds are regarded as old but healing by granulation tissue should not be accepted as the inevitable outcome. Part of our obligation is to obtain a soundly healed wound in the shortest time. This infected granulating type of wound takes weeks and some times months to heal if left to granulate, nor is it wise to attempt a secondary suture. These wounds can be very easily treated by the "cure of excision and suture, as opposed to the prevention of the early treatment and it is on that account that this method has been investigated.

A number of granulating wounds, practically all infected were submitted to a strict uniform opera-

tive detail described by the author. In order not to obscure the effectiveness of the operative part of the technique, no particular attention was paid in any way to preoperative control of infection. No case was especially selected. A wound was decided, crudely perhaps, to be suitable for suture simply when it looked clean there was no bacteriological control. The bacteriostatic agents employed were sulfanilamide, sulfathiazole, and penicillin (which was probably some months old its strength was 5,000 units per gram) three separate series of cases were treated and each was given a different powder. The success of the technique was judged entirely by the healing of the wound and any degree of infection which may have developed. It has been estimated on a percentage basis for tabulation as follows:

	Pw cent
Completely healed on tenth day without infection and remained healed subsequently	100
1. Very minor stitch-hole infection; wound a little "grumbly" but dry and healed at second dressing on sixteenth day	90
2. Definite stitch-hole infection with some pus or discharge perhaps slight wound-gap in places, but dry and healed on twenty-second day	80
3. Infection prolonged after twenty-second day some definite breakdown of suture line likely to be some granulation	70
4. Failures and generally poor or worse results than in pre-tious group	below 70

Series 1 consisted of 10 cases. The bacteriostatic powder used was a mixture of penicillin and sulfanilamide in a proportion of 1 to 10. The wounds in this series were on the whole rather above the average size and the time interval between wounding and suturing was relatively long. The results were quite satisfactory 8 wounds of 10 (80 per cent) being completely healed within three weeks. The penicillin-sulfanilamide mixture was considered to be too strong and the series was discontinued after 10 cases.

Series 2 consisted of 28 cases. Sulfathiazole was substituted for sulfanilamide and the strength of the mixture decreased to from 1 to 20. The wounds were somewhat smaller than in the first group and the time interval was, if anything, some days shorter except in a few cases in which the delay before operating was due to a heavily infected wound. There was an improvement in the results over those of the first group some 25 cases of 28 (practically 90 per cent) being completely healed in three weeks, although 7 of these were "second-class" results. Five transverse wounds, 4 of them in the thigh, were healed completely on the tenth day.

Series 3 consisted of 18 cases. Penicillin was discarded and sulfanilamide used alone. The wounds in this group were smaller the time interval shorter, and the bacteriostatic agent weaker than in any of the other groups. The results were generally somewhat inferior only 14 wounds of 18 being healed within three weeks, 9 with "second-class" results.

The main result of the investigation is that 47 wounds of 56 (84 per cent) were healed completely

within three weeks of suturing and that 23 of these 47 wounds (nearly 60 per cent) were healed by first intention on the tenth day. The object of changing a granulating wound into a healed wound in a short time has thus been attained. Further in the failures no wound was rendered worse by the operation, and even the "poor" results were an improvement on the original condition of the wound. The combination of a strong bacteriostatic powder and a longer time interval before suture in series 1 and 2 has produced better results than the weaker powder and shorter time interval of series 3 in which, however, there have been more "second-class" results. This would suggest, in this type of wound, that there may be some definite advantage in delaying operation for some time, apart altogether from the degree of infection which may be present, although the poorer results may be due entirely to the weaker bacteriostatic powder employed. These powders can be used in many varieties of strength and mixtures and in conjunction with variations in the time-interval factor.

The causative missile has been mainly the high-explosive shell or mortar shell the nature of the missile causing the wound has had no obvious effect on healing, nor has the healing process been obviously affected by the location, situation, or direction of the wound. The direction of the new wound should be longitudinal. Longitudinal wounds are more easily repaired, and should do better mechanically than those which are transverse both to the axis of the limb and to the line of muscular contraction. Wounds are mostly opened up in a longitudinal direction at the time of the original operation so that the direction of the new wound in most cases is predetermined. The surface area of the granulating wound to be excised is of no consequence provided the skin edges after excision can be approximated for suturing without tension. The depth of the granulating wound has some bearing on ultimate healing, as this may harbor a potential source of infection. The healing of 47 of 56 wounds subjected to the treatment is a definite indication that the method of excision and suture can be applied to these infected granulating wounds with the expectation of obtaining a cure. Still better results can be obtained by the carefully planned administration of preoperative penicillin. The sulfonamides, in the presence of infection, are not strong enough to be used alone.

The advantages gained by the technique have been (1) a considerable saving in healing time, which can be estimated in days as against weeks of a granulation hill-up (2) a clean first-intention wound (3) a soft, painless, nonadherent scar and (4) a more rapid and more complete functional recovery.

CHARLES BARON, M.D.

Kerr A. B., and Werner H.: The Clinical Value of a Growth Promoting Substance in the Treatment of Indolent Wounds. *Brit J Surg* 94: 3 28

The results of a clinical trial of a tissue extract known to possess the property of stimulating growth

in tissue cultures is reported. The material used was a powdered preparation of sheep's heart as prepared by Werner and Doljanski, and designated H E P (heart-extract powder). A total of 36 cases of indolent ulcers, burns and wounds which had failed to respond to orthodox methods of treatment were treated with this substance. Of these cases 33 have fulfilled the authors' criteria of success. Only 3 failed to show an adequate response. The lesions were dressed daily or on alternate days. Treatment consisted of gentle cleansing with saline solution followed by light sprinkling of the wound with H E P. The lesion was then covered with gauze either soaked in saline solution or lightly impregnated with vaseline.

Within a week of the commencement of treatment a development of fresh pink granulations was usually to be noted on the base of the wounds. This was accompanied or immediately followed by obvious epithelial spread from the margins. Thereafter healing proceeded normally and the ultimate scars presented no unusual features.

The material was also used in preparing sites for grafting when previous skin grafts had failed to take with complete success. In several cases in which very large areas were pinch grafted H E P was applied beneath the dressings on one half of the area grafted, but no difference could be observed between the grafts on the treated and untreated areas. It is to be noted however that in these cases the dressings could not be disturbed for several days to permit repeated application of the powder. Unsuccessful attempts were made to correlate the bacteriological findings with the occurrence of nonhealing and also with the response to the powder made of heart extract.

It is concluded that growth stimulating substances are of value in the healing of wounds in man. Several incidental observations were made in this study: namely, in multiple wounds healing and non-healing tend to occur in all wounds simultaneously; also, the augmentation of the tendency to heal by growth-promoting substances may lead to an improvement in the general condition of the patient.

JOHN L. LINDQUIST, M.D.

Boston, R., and Kurman, R. Tetanus: A Report of 2 Cases Treated with Penicillin. *J. Am. Med. Ass.* 1945 127 26.

The authors present 2 cases of tetanus treated with penicillin. Each was given large doses of tetanus antitoxin and sulfadiazine. When relapses occurred penicillin therapy was instituted in heroic doses. The first patient, age twenty-two, was discharged and cured on the thirtieth hospital day, and the other, age nine, was discharged entirely cured on the twenty-fifth day after admission.

In view of the high mortality of tetanus even in cases which have been treated with large doses of tetanus antitoxin the addition of the penicillin apparently a life-saving measure.

CHARLES BARON, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Tanner, N. C.: A Critique of Gastroscopy. *Brit. M. J.* 1944 2 849.

From the beginning of the war until December 1943, 2,200 gastroscopic examinations were done on 1,738 patients. Four hundred and seventy repeat examinations were done mainly to follow the progress of ulcer while under medical treatment to confirm healing to observe relapses and less frequently to confirm doubtful diagnoses, particularly those of cancer. Examination of the 1,738 patients revealed 589 gastric ulcer lesions, 39 gastric and duodenal ulcers, 77 postoperative ulcers, 101 gastric cancers, 267 cases of gastritis, 296 cases of duodenal ulcer, and 262 cases of functional or extragastric dyspepsia with a normal stomach. The remainder were varied pathological entities and unsuccessful or incomplete examinations.

In this clinic the main usage of the gastroscopy was for diagnosis and observation of gastric ulcer. Of the 631 gastric ulcers, 159 were diagnosed solely by gastroscopy as they apparently had normal x-ray findings. There are several reasons for the difficulty in diagnosis of many of the gastric ulcers. For example, an acute ulcer may have been too shallow to retain barium or after a hemorrhage its base may be filled with blood-clot which prevents the entry of barium to the crater. Or there might have been considerable delay after hemorrhage in x-ray examination of the patients, during which time the ulcer could heal and the scarring be missed roentgenologically. In cases of this type gastroscopy may show a well marked crater, the cause of the bleeding. At other times large ulcers particularly in the neighborhood of the angulus, may be missed roentgenologically but are readily visualized with the gastroscopy. In addition, gastric endoscopy sheds a good deal of light on the progress of the ulcer during healing. It is undoubtedly the most reliable guide in assessing the progress or failure of healing under medical regimes.

The first impression was that most gastric ulcers heal when treated in the hospital whether the patients are on ulcer diet, alkalization or just taking the normal hospital dietary with no drugs.

Gastroscopy is not indicated when it is possible to visualize the duodenal ulcer with x-rays and the diagnosis is consistent with the symptoms. But when roentgenography is uncertain or the symptoms are suggestive of a gastric lesion, particularly in the fifth decade of life, gastroscopy may be of some help. Thirty-nine of the patients with duodenal ulcer in this series also had a gastric ulcer and cancer was also seen on 2 occasions when duodenal ulcer alone was suspected roentgenologically. The author agrees that even direct visualization of an excised ulcer of the stomach may not abide the truth as to its innocence or malignancy. Nevertheless one is rarely in doubt after gastroscopic visualization, because vitality appears to accentuate the differences and where such doubt exists a second inspection

after ten days of medical treatment usually gives the clue. Certainly it is well worth while to gastroscopically examine every ulcer that is not healing rapidly under medical management." Superficial types of cancer may be missed roentgenologically and in this series there were 13 cases of cancer which had been considered benign or had not even been diagnosed roentgenologically.

There were 77 stomachs examined after operation, some merely for the purpose of investigation rather than for the suspicion of recurring ulcer. Inasmuch as this field is notably difficult for roentgenology gastroscopy is always advisable if anastomotic ulceration is suspected. In the absence of a gastrojejunal ulcer the stoma usually remains open. However if there is an ulcer on the jejunal side edema and spasm of the stoma may obscure the lesion. If there is a marginal ulcer on the gastric side, it can be easily visualized.

The diagnosis of gastritis still remains difficult. It is hard to know where the normal ends and the abnormal begins. In general, the gastric mucosa may be divided into three groups. The thick, with the *arcae gastricae*, is clearly seen as well as the medium and finally there is the thin which may be so thin that the submucosal vessels may be vis-

ible through it. Of the 49 patients with gastritis and a thick mucosa, 32 had severe symptoms. In only 4 of the 155 cases with a medium mucosa, was the condition severe enough to be a likely cause of the symptomatology. Of the 63 patients with gastritis presenting a thin or atrophic mucosa, 39 had severe symptoms.

The gastroscope is therefore most useful for pre-operative investigation. It can avoid unnecessary extensive and radical gastrectomies. It may even visualize such lesions as gastric diverticulum mucosal polyp and an occasional gastric carcinoma missed by the surgeon at laparotomy.

In view of the usually direct relationship between thickness of the gastric mucosa and its acid-pepsin secretion potentialities, some help may be gained in considering whether radical surgery—gastrectomy or palliative gastrojejunostomy—may be more advisable. The patients with thick mucosa are usually more likely to experience recurrent ulceration.

It is not the purpose of the author to make comparisons between gastroscopy and roentgenology. The methods are, of course, complementary and this study is intended to show the place that gastroscopy is making for itself in medicine.

SAMUEL J. FOGELSON, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Jacobs, E. A. Culver G. J., and Koenig, E. C.:
Roentgenological Aspects of Retroperitoneal
Perforations of the Duodenum *Radiology* 1944
43 565.

Perforation of the duodenum occurs most frequently into the free abdominal cavity. The clinical signs and roentgen appearance of this are well known. Early treatment has resulted in a surprisingly low mortality.

A retroperitoneal perforation of the duodenum is encountered in some cases of peptic ulcer and especially following trauma. About 10 per cent of all ruptures of the gastrointestinal tract occur in this part of the bowel and one-third of them are located retroperitoneally as a rule in the second and third portions of the duodenum. The mortality rate continues around 90 per cent.

The clinical picture is characterized by the fact that the trauma itself which usually is of the blunt type, elicits comparatively few symptoms. Only several hours later with the advent of the effects of the extravasation have the symptoms become marked. The duodenal contents rapidly infect the surrounding structures with the result that retroperitoneal cellulitis and necrosis set in and eventually lead to generalized peritonitis.

According to Miller the findings at operation are practically pathognomonic. The extravasated blood and duodenal contents are found either in the root of the transverso mesocolon or in the root of the mesentery of the small bowel or both, and in the intervening retroperitoneal space, very often extending somewhat to the right of the kidney. The tumor usually is crepitant since it contains gas.

The roentgen diagnosis is based on the visualization of this gas which often produces a rather wide spread emphysema. It is interesting however that although retroperitoneal perforations of the duodenum have been reported in the literature scores of times and emphysema was noted (clinically at operation, or at autopsy) in approximately 80 per cent of the cases, there are only 3 instances in which the diagnosis was made by roentgen study. The authors briefly review these 3 cases and add 2 of their own.

The first of the authors' cases clinically suggested possible perforation of the ascending colon and a scout film of the abdomen taken the day after injury revealed no evidence of free air or emphysema. Autopsy showed an acute perforation of the anterior wall of the third portion of the duodenum leading directly into the root of the mesentery with the formation of a huge, fetid dissecting retroperitoneal phlegmon, but no evidence of interstitial emphysema. The second case resulted in recovery following conservative treatment, and although the diagnosis

was not proved beyond doubt the roentgen findings indicated retroperitoneal perforation of the duodenum. There was a streak of air extending along the left side of the spine through the diaphragm presumably along the great vessels to the inferior mediastinum and another streak branching off underneath the left leaf of the diaphragm apparently between the muscle and the parietal peritoneum. This appearance did not change with shift of position of the patient.

The authors include a schematic drawing showing that the extravasated material from a retroperitoneal perforation of the duodenum tends to extend along on or several of the following courses according to the location and duration of the perforation: (1) along the root of the transverse mesocolon (2) along the root of the mesentery of the small bowel (3) along both an I in the intervening space (4) over the right (rarely the left) kidney (5) downward along the root of the mesentery of the ascending colon and cerum (clinically this may simulate and occasionally has been diagnosed as appendicitis or appendicitis abcess) (6) downward along the psoas muscle to the brim of the bony pelvis or to Poupert's ligament simulating a psoas abscess and (7) along the great vessels through the diaphragm into the inferior mediastinum.

The opinion is expressed that a roentgen diagnosis of retroperitoneal perforation of the duodenum should not be difficult in most instances. Roentgenograms should be made with the patient in the supine the upright the left lateral decubitus, and the lateral positions. In case of negative findings examination may be repeated after a few hours unless immediate surgical intervention is indicated.

T. LEUCUTIA, M.D.

Habbe J. E. and Wright H. H.: A Ray Evidence of Old Forgotten or Previously Undiagnosed Fractures. *Radiology* 1944 43 531

The authors report a series of old healed fractures, involving practically every major part of the skeleton which had gone undiagnosed from a few months to a number of years. In some instances a subsequent second injury led to the discovery of the old fracture. In others routine survey examinations permitted recognition of the previously missed fracture. From the medicolegal standpoint it is important that most of these patients could not recall any injury that might have accounted for the fracture. This applies especially to certain fractures of the carpal scaphoid of the middle and lower ribs of the metatarsal and metacarpal bones, and of all the phalangeal bones. The functional recovery as a rule was excellent and later the roentgen deformities of the affected bones constituted the sole positive evidence that there was a traumatic injury. It is the authors' contention that under such circumstances

the roentgen findings must be accepted at their full value, even in apparent contradiction to the history of the patient. The fractures may be placed in three categories (1) undiagnosed, (2) untreated or at least inadequately and unorthodoxically treated and (3) ultimately forgotten.

The cases described include unusual fractures of the seventh to twelfth ribs of the manubrium sternal of the carpal scaphoid of the distal radius and ulnar styloid of the metatarsals, metacarpals, and phalanges of the calcaneus of the vertebral bodies of any location of the bones of the pelvic girdle and of the zygomatic arch—20 cases in all.

Numerous very instructive roentgenograms are used to illustrate the points in question. It is recommended that in all such instances roentgenograms in multiple positions be made whenever possible.

Spear, F. G., and Tansley, K.: The Action of Neutrons on the Developing Rat Retina. *Brit. J. Radiol.* 944 17 374

The authors, in collaboration with Gluecksmann have published since 1936 a series of articles dealing with the dependence of degeneration upon mitotic activity in developing tissues exposed to small doses of x rays or gamma rays. In the present article they investigate the problem as to whether a similar effect occurs with the neutron rays. As in the previous experiments, the immature rat retina was chosen for the testing.

The irradiations were carried out in co-operation with Aebemold on the 37 inch, 80-ton cyclotron at Professor Lawrence's Laboratory in Berkeley California.

Two-day old rats were used and certain precautions were taken to insure that adequate maternal care was provided, a point of considerable importance. The whole body of the rat was exposed lots of 4 or 5 rats being placed in one "layer" in a

small cardboard box with a perforated lid and immobilized with cotton wool.

The cyclotron operated at 8 mv and from 60 to 80 μ A ion beam, the neutrons being produced by the Be-D reaction. The beam was passed through a suitable lead and water tank collimator and the radiation traveled a distance of 70 cm. to the rats. The dose was measured by a Victoreen ionization chamber and 1 n was considered to be 1 roentgen (as calibrated for x rays) although the unpublished work by Aebemold and Lawrence and a personal communication by Gray seem to indicate that 1 n probably equals from 2 to 2.5 roentgens of gamma rays.

Amounts of from 2.5 n to 60 n were administered, the exposure times varying from three-fourths minute to twenty-four minutes.

After exposure the rats were returned to their mother for from one and one half to seventy two hours and were then killed either by decapitation or by ether. The two eyes were dissected out and fixed in Zenker's solution. The corresponding controls were killed at the same time. After paraffin embedding, one eye from each rat was dispatched to England. The other eye was analyzed at Berkeley.

The biological response was measured quantitatively in terms of the mitotic and degenerate cell counts. The results obtained were arranged tabularly and plotted in graphs. They were then compared with the data from the former gamma ray experiments.

In a general way it was noted that neutron radiation produced an initial fall in mitosis, which was followed by a return to a cell division characterized by a distortion of the normal phase ratio. Degenerate cells appeared between one and three hours after exposure. It is probable that the degenerate cell count is made up partly by cells killed outright and partly by injured cells which die when subsequent mitosis is attempted. This effect is similar to that observed in gamma irradiation.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Peterson, E. W., Bornstein, M. B. and Jasper H. H.: Effect of Morphine Sulfate on Persons Exposed to Simulated Altitude. *War Med Chic.* 1945 7 23

It is a foregone conclusion that the sick or wounded persons who are candidates for transport by air will have received or will receive morphine for the control of pain or shock. In such persons it becomes a matter of concern whether the effects of morphine on the body other than those of analgesia and sedation may seriously impair their ability to undergo air transport.

The results of this series of experiments illustrate that the pharmacodynamics of morphine in the dosage employed does not cause, in the majority of cases, a significant deviation in the oxygen saturation of arterial blood such as might be effected by the drug's action on respiration.

JOHN E. KIRKPATRICK, M.D.

Peterson, E. W., Bornstein, M. B. and Jasper H. H.: Effect of Sulfathiazole on Persons Subjected to Simulated Altitude. *War Med, Chic* 1945 7 29.

The result of this series of experiments indicates that the pharmacodynamics of sulfathiazole in full therapeutic doses did not cause any significant deviation of the oxygen saturation of the arterial blood nor was there any significant deviation to be seen in the electrical activity of the heart or the brain. It seems clear from the various objective methods that were employed in this investigation that under conditions of severe anoxia, sulfathiazole in the dosage employed failed to alter the subject's reaction to anoxia.

The experimental method employed in this study did not take into account observations on reaction time with and without sulfathiazole medication. It is noteworthy however that the subjects studied did not experience any change in the psychic manifestations of anoxia while they were saturated with the drug. It is not intended however to advance any opinion as to whether aircrew members would be fit for flying duty while taking sulfathiazole or other sulfonamide compounds.

Normal adult males receiving sulfathiazole in full therapeutic doses failed to show any significant deviation in oxygen-saturation levels in the blood in electrocardiograms, or in electroencephalograms when subjected to simulated altitudes of 20 000 feet.

Anoxia produced in the decompression chamber even at simulated altitudes of 20 000 feet failed to change in a significant manner the subjective reactions of human subjects to full therapeutic doses of sulfathiazole.

It is concluded that sulfathiazole in full therapeutic doses does not significantly alter the ability of normal persons to withstand the effects of altitude and it is concluded that the evidence does not contraindicate the use of this drug for wounded personnel who are to be transported below 10 000 feet or above 10 000 feet with supplementary oxygen.

JOHN E. KIRKPATRICK, M.D.

Robbins, S. L. and Tucker, A. W. Jr.: The Cause of Death in Diabetes. A Report of 367 Autopsied Cases. *N England J M* 1944, 231 865

The subject matter of this report is drawn from a study of 367 diabetic patients over the age of twelve they were studied at autopsy at the Mallory Institute of Pathology during the years 1932 to 1942 inclusive. For purposes of comparison, autopsies were reviewed for anatomic causes of death in approximately 2,800 consecutive patients. In 268 patients of the diabetic group adequate histological material was reviewed to evaluate the frequency of histopathological changes. The clinical impression that the diabetic patient lives as long as the non diabetic was confirmed. However the diabetic patient is more likely to encounter the hazards of coronary occlusion peripheral vascular disease infections of the extremities, and acute pyelonephritis. As regards renal changes in the diabetic group glycogen nephrosis was present in significant degree in only 42 per cent of the cases while intercapillary glomerulosclerosis was present in only 20 per cent.

WALTER H. NADLER, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Keeney E. L., Ajello L. and Lankford E.: Studies on Common Pathogenic Fungi and on Actinomyces Bovis. In Vitro Effect of Fatty Acids. In Vitro Effect of Sulfonamides. In Vitro Effect of Penicillin. *Bull Johns Hopkins Hosp.*, 1944 75 377 393 410

The fungistatic and fungicidal effect in vitro of sodium valerate, sodium caproate, sodium caprylate, sodium caprate, and sodium undecylenate on the common pathogens and on actinomyces bovis has been studied and compared with sodium propionate. Sodium caprylate, sodium caprate, and sodium undecylenate are usually more fungistatic for the common pathogens and for actinomyces bovis than sodium propionate sodium valerate and sodium caproate. However sodium propionate inhibited the growth of trichophyton mentagrophytes microsporon felineum and histoplasma capsulatum equally as well as the longer chain, fatty acid salts, and was superior to all other preparations in its effect on blastomyces dermatitidis. Fungicidal activity is acquired as the fatty-acid chain is lengthened. Sodium

caprate and sodium undecylenate, though not strong fungicides, possess more fungicidal activity than sodium caprylate, sodium caproate, and sodium valerate. Sodium propionate does not possess fungicidal activity.

The relative toxicity of the fatty-acid salts for albino mice has been determined. The compounds enumerated in the order from lowest to highest degree of toxicity are sodium caproate, sodium valerate, sodium propionate, sodium caprylate, sodium caprate, and sodium undecylenate. The in vitro effect of sodium caprate or of sodium undecylenate on the fungi responsible for the cutaneous mycotic infections is sufficiently impressive to warrant the clinical trial of either preparation in the treatment of *trinea pedis*, *trinea cruris*, *trinea glabrata*, and *trinea capitis*. The in vitro effect of sodium caprate and of sodium undecylenate on the fungi responsible for the deep mycotic infections is impressive. However the clinical trial of these compounds in the treatment of the deep and the systemic mycotic infections and in actinomycosis should be withheld until animal experiments have been performed.

The fungistatic and fungicidal effect of sodium sulfathiazole, sodium sulfadiazine, and sodium sulfamerazine, in vitro, on the common pathogenic fungi and actinomyces *bovis* has been studied. The inhibiting effect of these sulfonamides on the growth of the fungi that produce the superficial mycotic infections, that is, trichophyton mentagrophytes, trichophyton rubrum, epidermophyton floccosum, microsporum audouinii, microsporum felineum and candida albicans, is not sufficiently impressive to warrant their use in the treatment of the skin infections that they produce. The inhibiting effect of these sulfonamides on the growth of the fungi that produce the deep and the systemic mycotic infections, that is, cryptococcus neoformans, blastomyces dermatitidis, sporotrichum schenckii, coccidioides immitis, phialophora pedrosoi, and histoplasma capsulatum, is only impressive for phialophora pedrosoi and histoplasma capsulatum, the respective causes of chromoblastomycosis and histoplasmosis. The clinical trial of sodium sulfamerazine in the treatment of chromoblastomycosis, and sodium sulfathiazole in the treatment of histoplasmosis is warranted. The inhibiting effect of these sulfonamides on the growth of actinomyces *bovis* is not spectacular and conservatism should be displayed in regard to expectancy of cure from their use in the treatment of human actinomycosis.

The fungistatic and fungicidal effect of purified penicillin, in vitro on the common pathogens and on actinomyces *bovis* has been studied. Purified penicillin in a concentration of 10 oxford units per cubic centimeter of culture media failed to inhibit the growth of trichophyton mentagrophytes, trichophyton rubrum, epidermophyton floccosum, microsporum audouinii, microsporum felineum, candida albicans, blastomyces dermatitidis, sporotrichum schenckii, cryptococcus neoformans, coccidioides immitis, phialophora pedrosoi, and histoplasma cap-

sulatum. Penicillin, in many instances, stimulated the growth of pathogenic fungi in vitro. The use of penicillin in the treatment of the superficial and the deep mycotic infections is unwarranted and contraindicated. Penicillin in a concentration of 0.01 Oxford unit per cubic centimeter of culture media inhibits and apparently kills the actinomyces *bovis*. Clinical reports on the use of penicillin in the treatment of human actinomycosis have not been sufficiently impressive to warrant unrestricted enthusiasm on the part of the clinician for this mode of therapy.

W. H. NIXON, M.D.

Todd, E. W., Turner, G. S. and Drew, L. G. W.: Temporary Character of "Fastness" of Staphylococci to Penicillin. *Brit. M. J.* 1945, 1: 11.

It is believed that micro-organisms which have been made resistant to bacteriostatic drugs or to antibiotic agents by continued subcultures in increasing quantities of the antibacterial substance will remain fast after many subcultures in ordinary laboratory media. This has been demonstrated with the micrococcus lysodeikticus made resistant to lysozyme wherein after repeated subcultures extending over nine months in ordinary culture media, the resistance was fully maintained and a *sella* pyridine-fast strain of pneumococcus Type I remained resistant after 30 subcultures in broth.

Consequently it is assumed that bacterial resistance to sulfonamides is of a permanent character. Contrariwise, it has been found that two strains of coagulase-positive staphylococci having been made penicillin "fast" by cultivation in increasing quantities of penicillin and subcultured daily in broth without penicillin showed a rapid fall in resistance to penicillin. Therefore it appears that fastness of staphylococci to penicillin is not a permanent characteristic.

STEPHEN L. ZIMMER, M.D.

DUCTLESS GLANDS

Womack, N. A.: Thyroiditis. *Surgery* 1944, 16: 774.

Thyroiditis is encountered clinically under three main types: (1) acute suppurative thyroiditis, (2) acute nonsuppurative thyroiditis, and (3) chronic degenerative thyroiditis.

Acute suppurations are of bacterial origin and are extremely uncommon. The onset is abrupt and occasionally associated with chills. Pain is the outstanding symptom. The neck is held fixed. Swallowing is painful and hoarseness may be present. Since the advent of chemotherapy acute suppuration of the thyroid gland is becoming less frequent. Should an abscess develop, surgical drainage is indicated. The surgical incision should give adequate drainage but care must be taken not to break through the inflammatory barriers of the neck more than necessary and, in particular the pathways to the mediastinum must be protected.

Nonsuppurative acute thyroiditis is seen more frequently than the suppurative type. However, since surgical interference is seldom indicated little

is known about the disease. In view of the fact that one-half of the cases give a history of recent upper respiratory tract infection and that occasionally the process goes on to suppuration it is probable that the instigating factor in the inflammation is bacterial. The onset is not so abrupt as in the suppurative type fever is slight or absent. The gland is enlarged and tender but swelling and tenderness of the adjacent tissues are not so pronounced. The lesion is usually self limited and subsides in from ten to twelve days. Chemotherapy is suggested.

Chronic degenerative thyroiditis is of two types one described by Riedel and the other by Hashimoto. The author agrees with Graham and McCulloch who believe these are separate clinical and pathological entities and thereby disagrees with Ewing who believes that they are different stages of the same disease.

The dominant lesion of Riedel's disease is fibrosis. In about one third of the reported cases this is limited to one lobe or to part of one lobe. Extra glandular fibrosis is present in later stages. The involved gland is hard and white and not appreciably enlarged although when the surrounding muscles and vessels are involved the outlines of the gland are not too distinct. The most conspicuous clinical features are related to the fibrosis. If this is mild a slightly enlarged very hard gland may be the presenting symptom. Hypofunction of the gland may be present. Invasion of the adjacent structures by fibroblasts brings on symptoms of obstruction. Compression of the jugular veins with resulting edema and pressure on the esophagus causing dysphagia are usually earlier than severe tracheal obstruction. It is often confused with cancer and microscopic examination may be necessary to establish a correct diagnosis. Treatment is entirely related to the relief or prevention of obstruction. When only one lobe is involved resection of this lobe and the isthmus is generally feasible. When the entire gland is involved, subtotal resection is usually dangerous and removal of the isthmus in order to free the trachea may be all that can be done.

The classical picture of struma lymphomatosa (Hashimoto) as generally considered presents several differences. The entire gland is usually involved. It is lobulated very thick and its surface is smooth. The only extraglandular attachments are tracheal and these are never extensive. The gross picture is easily explained when the gland is studied microscopically. The yellow trabeculated, meaty appearance of the cut surface is due to lymphoid overgrowth. Lymphoid follicles are prominent but the lymphocytes themselves as well as the follicles differ in no way from those encountered less extensively in exophthalmic goiter status lymphaticus or even Riedel's struma the chief difference appears to be a quantitative one.

The chief damage produced by struma lymphomatosa is that of obstruction and here the indication for surgical extirpation must lie.

EARL O. LATIMER, M.D.

Nussey, A. M.: The Treatment of Hyperthyroidism with Thiouracil. *Brit. M. J.* 1944, 1, 745

Thiouracil and thiouracil probably act by preventing the union of tyrosine and iodine into diiodotyrosine which is a precursor of thyroxine. Once thyroxine is present in the body thiouracil and its derivatives cannot stop its action. This would explain the lag observed in the clinical response to thiouracil and thiouracil, and is in keeping with the observation that desiccated thyroid gland is capable of counteracting these substances in experimental animals.

At present it is possible when treating patients to inadvertently exceed the optimum dose, which causes an increase in the size of the gland and a condition resembling myxedema. Other complications known at present are granulopenia, thrombocytopenia, enlargement of the lymph glands and spleen fever and skin eruptions. Thiouracil is less toxic than thiouracil.

The author reports 27 cases of thyrotoxicosis in patients treated by these drugs for periods varying from three weeks to a year. A period of from two to eleven weeks was required to obtain a satisfactory clinical response. Doses of 0.2 gm. of thiouracil were given three times daily for a period of from three to five weeks, after which the dose was gradually reduced until the lowest dosage compatible with the patient's well-being was reached.

Signs of improvement were usually apparent in from ten to fourteen days after the beginning of treatment. Severe thyrotoxicosis frequently responded as quickly as the moderate type. Restlessness was usually the first symptom to disappear and then the flushed and moist skin became paler and drier the staring expression and the shiny appearance of the eyes faded the weight increased the tremor of the fingers became less the vascularity of the gland diminished and, finally tachycardia subsided. It was in the milder cases that tachycardia persisted the longest. In nearly all of the cases the basal metabolic rate returned to normal. Exophthalmos was unaffected by the drug nor did enlargement of the thyroid diminish to any extent. Mild myxedema occurred in a few cases, but disappeared when the dosage of thiouracil was reduced.

For a maintenance dose, the patients were usually given 0.2 gm. of thiouracil twice daily for from two to four weeks after they left the hospital. Later most of them were maintained on from 0.2 to 0.1 gm. or even 0.05 gm. daily. In a few cases all medication could be stopped. In no case was there an alarming fall of the white-cell count.

The author concludes that the drug although not devoid of risks, is much safer than operation.

EARL O. LATIMER, M.D.

Cole, W. H.: Factors Influencing the Operability and Mortality Rate in Goiter. *Surgery* 1944, 16, 688.

The marked reduction in the mortality rate following thyroidectomy during the past one or two decades has been due primarily to our increased

knowledge and application of physiological principles, particularly as related to preoperative and postoperative care. Preoperative preparation is exceedingly important in patients with severely toxic goiter.

The major factors in this preparation of the patient include (1) the administration of iodine or thiouracil (2) an increased caloric intake, (3) the conservation of energy (4) the reduction of psychic trauma (5) the treatment of complicating disease and (6) miscellaneous therapy.

Appreciating that the mortality rate is greatly dependent upon preoperative treatment, the author has adopted certain prerequisites which must be met in his clinic before a patient is considered safe for bilateral thyroidectomy. These prerequisites are (1) a gain in weight, (2) a resting pulse rate below 110 (3) a basal metabolic rate below 50 (4) response to iodine or thiouracil and (5) no untreated complications. Of this group of prerequisites, gain in weight is the most important. It is an unforgivable error to subject a patient with severe toxic goiter to bilateral thyroidectomy unless he has shown a gain in weight.

Thiouracil gives promise of revolutionizing our methods of preoperative care and may make operation unnecessary in many patients. However it is doubtful if the mortality rate may be appreciably lowered in the clinics reporting the best results, largely because relatively few of the deaths encountered in such series of patients will be related to thyrotoxicosis itself.

The mortality rate in the author's series of 936 thyroidectomies was 1.06 per cent. It was lower in toxic diffuse goiter than in either of the two types of nodular goiter. Although almost one half of the deaths must be considered in the preventable class, the causes were extremely variable. Three patients died of acute heart failure, and 2 died in crisis. There was no duplication in the other causes of death. The factors (other than coincidence) which might be responsible for a lethal outcome include (1) inadequate preparation (2) wrong choice of time for operation (3) lack of appreciation of the dangers of complications (4) errors on the operating table and (5) insufficient vigil in the postoperative care.

It should be emphasized that many of the precautions described here will be of only slight importance in the great majority of patients who respond to thiouracil. However since an occasional patient will be sensitive to the drug or will not respond to it, information gained about severely toxic patients through long experience should not be cast aside.

FARL O. LATIMER, M.D.

Holmes, J. M., and Cowan, J. M.: The Meningococcal-Adrenal Syndrome; 5 Cases with 1 Recovery. *Lancet*, Lond., 1945, 248-13.

Meningococcal infections may be classified in the following main groups:

1. *Meningococcal septicemia*. (a) Acute fulminating septicemia, with extensive purpuric eruptions

and adrenal hemorrhages, death often occurring from circulatory failure a few hours after onset. (b) Chronic septicemia with intermittent pyrexia, petechiae and skin lesions resembling erythema nodosum occasionally arthritis, and a later development of meningitis.

2. *Meningitis*. Acute, subacute, and chronic.

3. *Encephalitis*. Cases in which the intracranial lesions are far in excess of the meningitic. Deep coma may be present, and the signs of meningitis may be masked. The encephalitic type of onset often accompanies the acute adrenal syndrome, the characteristic purpuric rash and circulatory failure being seen in both.

The adrenal syndrome (Waterhouse-Friderichsen) or the meningococcal adrenal syndrome is characterized by a sudden onset of a fulminating septicemia, with cyanotic pallor like the heliotrope cyanosis in influenza septicemia. Later multiple cutaneous petechiae and possibly massive purpuric hemorrhages occur. The pulse is rapid, of poor volume, and it may be almost imperceptible. The blood pressure is low. Respiration is rapid and shallow and may become of the Cheyne-Stokes type. Consciousness may be dulled. In untreated cases, death usually occurs within twenty-four hours.

The difficulty in this type of case is in making the diagnosis and in beginning treatment as early as possible. Frequent blood-pressure readings should be taken in all cases of severe meningococcal meningitis since an abnormally low blood pressure is the only reliable early sign of adrenal failure. If treatment is withheld until the characteristic cyanosis and rapid shallow respiration appear it may be too late to be effective.

The postmortem findings suggest that death is due to circulatory collapse from a severe diminution of the blood volume. Widespread edema of the lungs and the interstitial tissues was found. In 2 cases there was an enlargement of the thymus and lymphatic glands. It is suggested that this may be a factor in determining the susceptibility of the adrenal glands to infection.

Vigorous measures must be taken to combat the circulatory failure. The sulfonamide drugs alone appear to be useless. In the few recorded cases in which treatment was successful, the sulfonamide therapy was supplemented by large intravenous infusion of saline or glucose-saline solution, and injections of adrenocortical extract or dexamethasone. Plasma rather than glucose-saline transfusion may be advisable.

SAMUEL KARK, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Herbst, P. A., and Manges, W. E.: Melanoma of the Small Intestine. *Arch. Path.*, Chlc., 94: 39-2.

The increasing number of melanomas reported, despite the merely passing comments concerning these tumors as found in the literature, induced the

Fig. 1. a, Left, Segment of small intestine showing at least 22 blackish tumors of various shapes and sizes. b, Photomicrograph of a section of the small intestine showing tumor cells diffusely infiltrating the submucosa, breaking through the submucular mucosa, and partially replacing the vessels. Although finely granular brown pigment is abundant within the cytoplasm of the tumor cells, it cannot be seen with this magnification. (Hematoxylin and eosin)

authors to undertake this study. They have collected 25 cases, 9 primary melanomas of the small intestine and 16 of metastatic origin. The great frequency of skin melanomas was apparently not studied thoroughly enough to determine their metastases to the intestinal tract. Twelve of these melanomas were found in the last 5,000 autopsies done at the Jefferson Medical College Hospital, Philadelphia, Pennsylvania.

The authors state the purpose of this report as follows: (1) to describe 5 cases of melanoma of the small intestine; (2) to draw special attention to their accompanying clinical manifestations; and (3) to consider whether a melanoma can arise as a primary tumor of the small bowel or whether such a growth is in every case secondary to a primary focus elsewhere. A detailed report of the 5 cases is given. Figures 1 a and b are very instructive.

The knowledge gained by these studies and from the additional 5 cases (30 cases now reported) is very definite. It stresses abdominal pain with or without symptoms of intestinal obstruction, combinations of pain and fullness in the epigastrium, nausea and vomiting, anorexia, constipation or diarrhea, tarry stools, distention and tenderness of the abdomen and increased peristalsis, sometimes a liver tumor may be held responsible for the symptomatic mentioned. Sudden colicky abdominal pain followed by

nausea, vomiting and constipation may be the first and only indication for prompt operation—this is true particularly in cases of intussusception. The immediate prognosis is not entirely hopeless. 4 of the operative cases ended in recovery. One patient lived comfortably six months and then died of a lung metastasis. One patient operated upon for obstruction with resection of a tumor, was operated upon again one and one half months later for intussusception and another tumor was removed. Six months later this patient was still well. Another patient with 2 intussusceptions caused by 2 tumors, recovered but died six weeks later. The fourth patient was reported as recovered but no record of the ultimate condition was given.

Primary melanoma generally occurs in the skin or the eye. Reports of primary melanoma in the small intestine are questionable as (1) melanoblasts are found only in the skin and in mucous membranes of ectodermal origin; melanoblasts are not found in the large intestine above the mucocutaneous junction of the rectum and have not been demonstrated in the small intestine; (2) the involvement of the small bowel is the same whether or not a primary melanoma has been located elsewhere; (3) delayed metastatic growths often appear years after a mole has been removed; (4) moles that grossly and histologically appear to be benign are known to have pro-

apparent sequence is—glycogen, neutral fat anisotropic lipoids.

Xanthoma cells The stroma of 26 tumors showed this type of cell. The xanthoma cells do not appear to be neoplastic in character.

Dermoplasia. This was seen in 18 solid tumors of group 4. Interstitial fibrosis is about equally common in the more static forms of solid tumors of group 4 and is noninvasive in appearance. It distorts the arrangements of cells in the cords and islands to a marked degree.

Anaplasia This may occur in any type of tumor tissue. Isolated anaplastic areas are the most frequent source of metastases. In 18 tumors it was so extensive that analysis of their basic character was impossible.

Capsules Capsules are without significance. No conclusion can be drawn as to the liability of these tumors to spread by metastasis on the basis of the presence or absence of a capsule.

Lumens When the solidification of a papillary tumor is imperfect, lumens may be expected. They do not have regular outlines. Potential lumens are often made apparent only by hemorrhage into them or by extravasation of fluid. Thirteen tumors of groups 2 and 4 were predominantly cystic as a result of this.

Chronic inflammatory change. Extensive lymphocytic and plasma-cell infiltrations were seen in 11 tumors of group 2.

Wilms tumors occurring in adults These may show the papillary type of renal cancer. Three excellent examples were seen: papillary clear-cell cancer with rhabdomyosarcoma, group 1, 2 and 4 tumor with rhabdomyosarcoma, and group 3 cystic cancer with large quantities of adult smooth muscle.

Embryonal carcinomas. Seven solid and 2 alveolar cancers of this type occurred in the series.

Adenocarcinoma. Adenocarcinoma of the kidney does not differ greatly from that of other organs. Nine of 15 tumors thus diagnosed showed some atypical traces of tumor tissue of group 1 type. The 6 others could not be identified as renal tumor on a histological basis. The use of the term "adenocarcinoma" should be avoided elsewhere (not in group 1) in the nomenclature of renal tumors.

Opaque cell papillary tumor These are smooth cell, opaque-cell, or solid-cell cancers. The cells are larger from a broadening out of the cytoplasm which is basophilic and pale but without any granulation. The nuclei have prominent nucleoli.

SAMUEL KAHN, M.D.

EXPERIMENTAL SURGERY

Smith, L. W., and Livingston, A. E.: Wound Healing. An Experimental Study of Water-Soluble Chlorophyll Derivatives in Conjunction with Various Antibacterial Agents. *Am. J. Surg.* 1945 67 30.

A preliminary study of the water-soluble chlorophyll derivatives in various ointment bases in over

200 experimentally induced lesions in guinea pigs showed an acceleration of healing of approximately 25 per cent in time in 71 per cent of the lesions treated topically with chlorophyll as compared with those treated by the ointment base alone.

Further studies were carried out upon a series of 193 guinea pigs with bilateral symmetrical infected surgical lesions 1.0 cm. in diameter which were similarly treated by the topical application of 1 per cent chlorophyll ointment combined with various of the sulfa drugs, with penicillin and with tetrodine. Twenty four animals were used in the experiment with each antibacterial agent, being divided into three equal groups of 8 animals: one third were treated with the base alone, one third with the base plus chlorophyll alone, and the final third with base plus antibacterial agent alone.

The topical use of penicillin in strength of 250 Oxford units per gram of ointment combined with 1 per cent chlorophyll gave the most spectacular results with healing complete in ten and six tenths days as compared to fourteen and three tenths days after treatment with chlorophyll alone and fifteen days after the use of penicillin alone, an acceleration of nearly 35 per cent.

In general the sulfa compounds in combination with chlorophyll showed some acceleration of healing through their control of infection which appeared to be roughly proportional to their solubility. Experimental carboxysulfathiazole was by far the most effective of these sulfa compounds, nearly equalling penicillin in that respect. Sulfanilamide, sulfamerazine and sulfasuxidine alone in the ointment base actually caused delay in healing, and tetrodine employed in the same manner was of about the same order of effectiveness as sulfanilamide, sulfathiazole and sulfadiazine.

Experiments carried out on 8 dogs with larger wounds gave comparable results to those described in the guinea pig studies.

A small series of guinea pigs treated by chlorophyll combined with various agents as a dusting powder gave less clearly defined results, and further studies do not seem warranted. The ideal ointment base proved to be entirely satisfactory and well adapted for clinical use.

A discussion of the clinical possibilities of chlorophyll in combination with the various antibacterial agents is presented and its importance in the healing of chronic types of ulcerative lesions is stressed.

JOHN E. KIRKPATRICK, M.D.

Hartman, F. W.: Curling's Ulcer in Experimental Burns. *Ann. Surg.* 1945 121 54.

The material used as the basis for the author's article consists of 32 instances of gastric and duodenal ulceration occurring in the course of experiments on 80 dogs in which third-degree burns were produced on from 50 to 60 per cent of their bodies while the animals were under morphine and ether or morphine and chloroform anesthesia. Following the procedure, a liberal use of morphine and com-

plete dressings kept the animals comfortable, as evidenced by the fact that they were active and retained a good food intake until the terminal stages.

In the first series there were 47 third-degree burns involving from 50 to 60 per cent of the body surface, and 13 of these were associated with ulceration of the duodenum or stomach. Thirty of these burns were dressed with tanning agents, such as tannic acid, ferric chloride, and silver nitrate. In this group ulceration occurred only twice, or in 6.6 per cent, and then only in those having wet dressings. Of the 17 burns dressed with vaseline, lanolin, and scarlet r ointment, 11 or 64.7 per cent, showed ulceration. In the second series of 33 animals with burns of similar type, all were dressed with sterile vaseline, and 21 or 63.6 per cent, showed duodenal ulceration.

The gross examination of the duodenal ulcers revealed various erosions—from the most superficial mucosal lesions to penetrating invasive lesions with hemorrhage or perforated punched-out lesions with peritonitis. The inflammatory infiltration was mild (or absent) in most cases, and an acute exudate reaction was found in only 1 section. A few healed ulcer craters and large scarred areas of the duodenal wall were observed.

A comparison of the gastric contents (both after fasting and after the injection of 50 cc. of 5 per cent alcohol) of the normal dog and of the burned dog at various stages showed that both the free hydrochloric acid and the total acid were reduced sharply rather than increased. The other significant finding in the gastric contents was the blood, frequently seen as shreds and clots, and giving strongly positive chemical reactions. This, coupled with the appearance found at autopsy emphasizes the damage to the mucosa preceding ulceration or in the absence of ulceration. Hyperacidity as an explanation for Curling's ulcers is without support, according to the author's data, but normal acidity may be sufficient

to cause ulceration in the edematous, congested mucosa of these burned animals. Further it is quite possible that the usual alkalinity of the duodenal contents is reduced by mucosal damage and the developing general acidosis.

The 63 per cent incidence of Curling's ulcers in the two series of animals burned and dressed with vaseline and other bland applications, as contrasted with the 6 per cent incidence in the group burned in a similar manner and dressed with tannic acid or other tanning agents, indicates that an analysis of the two groups may suggest etiological factors. The animal whose wound is dry-tanned loses very little plasma from the body although the area beneath is always very edematous. The infection (if any) in such a wound is usually slight up until the fourth or fifth day when marginal separation of the eschar begins. The animal is comfortable and eats well after the first thirty-six to forty-eight hours. Marked acidosis rarely develops, and, barring liver necrosis, a good recovery with eventual healing of the skin defect is accomplished.

Animals treated with moist dressings of tanning agents have a course more like that of the animals dressed with bland preparations, except that necrosis and infection are somewhat reduced. With the bland dressings, the injured tissue rapidly begins to undergo autolysis. This, coupled with great and continued loss of plasma into the dressings, favors extensive infection with the various types of organisms listed. The appetite is reduced, so that despite careful feeding there is a marked weight loss, acidosis, septicemia, and coma, and convulsions are frequent.

Loss of plasma, rapid autolysis of injured tissue, with infection and acidosis are the factors which were observed in this group of animals, and these factors may logically be cited as the variables responsible for duodenal ulceration and death.

- Fatigue, Problems of, as illustrated by experiences in decompression chamber 157.
- Femoral vein, Ligation of for chronic occlusive arterial disease: review of 8 ligations, 465.
- Femur Fractures of: results of treatment of 179 patients, 55. evacuation of fractured: Tobruk plaster and other methods used in Middle East, 57. fractures of, in children, 8. ambulatory treatment of fractures of lower extremities: posterior approach to, 285. tuberculosis of greater trochanter and its bone, 274. practical points in plastic technique: two years' experience in forward surgery with Royal Army Medical Corps (mobile) casualty clearing station, 942. 943. 5th. slipping of upper epiphysis of diaphysis and therapeutic considerations, 455. internal fixation of fractures of neck of 463.
- Fibrin foam as hemostatic agent in rehabilitation neurosurgery 70.
- Fibrinogen, Clinical use of products of human plasma fractionation: use of products of and thrombin in surgery 203.
- Fibroids, Place of surgery in, of uterus, 70.
- Fibroma, Dupuytren's contracture: of palmar fascia, 54.

- Fistula**, Spontaneous gastrojejunal, eight years after operative gastrojejunostomy 114 treatment of traumatic aneurysms and arteriovenous, 134 congenital atresia of esophagus, with tracheoesophageal, 185 physiological observations on patients with external pancreatic, 356 analysis of 90 cases of transplantation of ureters for obstetrical vesicovaginal, 366
- Fluid**, Effect of intravenous, on dehydrated patients and on normal subjects, 136 medical progress, parenteral therapy with, estimation and provision of daily maintenance requirements, 243 rapid replacement of in hemorrhage and shock, 208 experimental study of histopathology of burns with particular reference to sites of loss of in burns of different depths, 321
- Fluorescein method** Use of in establishment of diagnosis and prognosis of peripheral vascular diseases, 215
- Flyers**, Problems of fatigue as illustrated by experiences in decompression chamber 157 obstruction of eustachian tube and barotrauma in air-crews, 169 traumatic deafness in combat 170 surgery in airborne division 469
- Flying**, Aerial evacuation of thoracic wounded, consideration of effects of altitude, 185 cerebrospinal-fluid pressure under conditions existing at high altitudes critical review 344 protective effects of preoxygenation on abdominal gas pain results of study of preflight breathing of oxygen on pain resulting from decompression to 35,000 feet, 407 acute high-altitude anoxia gross and histological observations in 27 cases, 407 aviation deafness, 421
- Foot**, Congenital talonavicular synostosis, 208 Lantounis periosteocapsuloplasty for congenital dorsal subluxation or congenital overlap of fifth toe 208 repair of surface defects of 226 strain of in services, 289
- Foreign Bodies**, Intrathoracic metallic, 112 localization of intraocular by means of contact lens, 249 nonmagnetic intraocular 420
- Fractures**, Of femur results of treatment of 179 patients, 56 evacuation after, of femur, Tobruk plaster and other methods used in Middle East, 57 Paget's disease, its pathological physiology and importance of this in complications arising from, and immobilization, 131 of femur in children, 131 march analysis of 106 cases, 131 march analysis of 100 cases, 131 observations on battle-casualty compound, and joint injuries in Middle East, 140 of temporal bone 191 ambulatory treatment of lower extremities, 211 march report of 307 cases new method of treatment, 212 studies on convalescence following nitrogen metabolism after, and skeletal operations in healthy males, 213 studies on convalescence following influence of diet on post-traumatic nitrogen deficit exhibited by patients with, 287 march statistical study of 47 patients, 287 march series of 58, 288, march series of 64 cases, 288 analysis of 359 flying-bomb casualties, 305 air lite new plastic medium for clinical immobilization, 306 cancellous chip bone-grafts report on 75 cases, 376 internal pin transfusion of analysis of 80 cases, 379 practical points in plaster technique two years of experience in forward surgery with Royal Army Medical Corps (mobile) casualty-clearing station, 1941 1943, 381 of xygomatic tripod, 419 use of longitudinal wires in bones in treatment of and dislocations, 461 sacral, and injuries to cauda equina, 461 internal fixation of neck of femur 463 internal derangements and, involving knee results of 150 consecutive arthrotomies performed at station hospital, 463, treatment of in combat area, 469 x-ray evidence of old forgotten or previously undiagnosed 477
- Frontal bone**, Osteomyelitis of treated with penicillin 90
- Furunculosis**, Treatment of multiple with penicillin, 231
- G** ALL bladder Preponderance of gallstones in women collective review 1 clinicopathological study of 100 cases of acute and chronic disease of, 40, cholecystitis advantages of operative treatment in definite untreatable disease, 354, sequelae of cholecystectomy 354 congenital absence of 437
- Gallstones**, Preponderance of in women etiological study collective review 1
- Gangrene**, Influence of estrogens on peripheral vasomotor mechanism, 218
- Gas bacillus**, Roentgen therapy in infection report of 9 cases with recovery 238
- Gas gangrene**, At Australian general hospital in Owen Stanley and Buna Gona campaign 65 3 cases of clostridium welchii infection treated with penicillin, 73 prophylaxis and therapeutics of clostridial infections, 162, new drugs active in chemotherapy of experimental, 229 in amphibious warfare in Pacific area, 394 collective review 411
- Castroectomy** Medical progress, late effects of total and subtotal, 36 studies on surgical convalescence sources of nitrogen loss after effect of high amino-acid and high caloric intake on convalescence, 40 subtotal, for duodenal ulcer 114 emergency for acute perforation of carcinoma of stomach with diffuse soiling of free peritoneal cavity, 190 complications and mortality in subtotal, for duodenal ulcer report of a two-stage procedure, 191 total clinical and physiopathological study 351
- Gastritis**, Chronic, and carcinoma of stomach 189
- Gastrointestinal tract**, Cancer of region of cardia and lower end of esophagus, 36 experimental observations on human ileocecal valve, 40, intubation studies of human small intestine review of a ten-year experience, 117 extrarenal uremia report of 2 cases due to pyloric obstruction 183 Meckel's diverticulum dyspepsia Meckel from heterotopic gastric mucosa, 193, length of small intestine, 196 acute perforated ulcer in West Scotland 262 acute perforated peptic ulcer in West Scotland, 263, primary malignant tumors of small bowel, 263 inflammatory stricture of rectum analysis of 192 cases, including 35 treated by rectosigmoid resection, 265 peptic ulcer in Canadian army (1940 to 1944) 351 healing of intestinal anastomosis, 352 renal tumors simulating disease of 445
- Gastroscope**, Visualization of rubber tip of differentiation from gastric ulcer 40 control of treatment of gastric ulcer by duodenal feeding with 432
- Gastroscopy** Critique of 475
- Gauze**, Hemostasis with absorbable, (oxidized cellulose) 151
- Gelatin**, Use of solutions of in treatment of human shock, 137 as substitute for plasma observations on administration to human beings, 304, use of specially prepared solution of as plasma substitute, 389 retention of intravenously infused, 396 evaluation of and pectin solutions as substitutes for plasma in treatment of shock histological changes produced in human beings, 467
- Genital organs (female)** Zondek's simplified treatment of secondary amenorrhea, 43 tuberculosis in, 120 changes in operative gynecology during last quarter-century 199 cyclic ovarian changes in artificial vaginal mu

- case, 373 study of commercially manufactured catamenial tampons, 74, deaths in gynecology 359 treatment of gonococcal vulvovaginitis, 439
- Genital organs (male) Male climacteric, its symptomatology, diagnosis, and treatment, 306 observations on pathological anatomy of benign prostate enlargement, 330 reconstruction of, 8 penile horn, 368 factors in male sterility: critical review of 135 cases, 370
- Genitourinary tract, Infestation of, by strychnine ster-cornalis, case report, 129 clinical use of penicillin in infections of, 30
- Glands, Aspiration biopsy of thyroid in evaluation of thyroid dysfunction, 5 6
- Glaucos, Clinical and pathological features of of spinal cord, 97
- Glycogen, Observations on some histochemical reactions in human placenta with reference to significance of lipoids, iron, and, 36
- Gout, Four hundred and ten cases of under general anesthesia with pentothal, 74, in children, 5 7 diffuse and adenomatous, and, induced by various agents, 409, in Southern States, 41 factors influencing operability and mortality rate in, 48
- Gonadotropin, And antihormone problem, 440 chorionic, and premenstrual values in normal pregnancy 443
- Gonorrhea, Sulfonamide-resistant, treated with urea and sulfonamide by mouth, 50 treatment of sulfonamide-resistant, with penicillin sodium, 5 one-day treatment of sulfonamide-resistant acute, with penicillin, 5 use of penicillin for resistant to sulfonamide compounds: report of 450 cases, 51 sulfonamide therapy of, 98 penicillin for treatment of chemoresistant, in female, 98 penicillin in sulfonamide-resistant, 28 penicillin X, 30 venereal diseases among migrant farm laborers of New Jersey 371 penicillin treatment of sulfonamide-resistant, results of multiple and single injection methods, 371 233 cases of sulfa-resistant, treated with 50,000 units of penicillin, 37 treatment of vulvovaginitis due to, 439
- Grafting, Biopsy as an accurate guide to decision of early skin, 470 modification of plasma fixation method (Sano) of skin, by use of hobbins and a mirror attachment, 471
- Grafts, Buccal mucous-membrane, in treatment of burns of eye, 24, closure of defects of lips with composite vermillion border-lined flaps, 67 nerve, from cadavers in human surgery 94, heterogenous skin, by coagulum-contact method, 143 fixation by plasma-thrombin adhesion of skin, 227 refrigerated skin, 228 cancellous chip bone report on 75 cases, 376 vaseline-gauze-contact fixation of split-thickness (Padgett) skin, 473 resplitting split-thickness, with the dermatome method for increasing yield of limited donor sites, 47
- Granuloma inguinale, Polyarticular arthritis and osteomyelitis due to, 54, penicillin in treatment of 30
- Grease gun, Injuries due to, 71
- Gullethor operation, Amputations, surgery and plastic repair 460
- Gynecology Changes in operative, during last quarter century 199 deaths in, 359
- Gyrocampa in Navy 57
- HANDS, Dupuytren's contracture fibrosis of palmar fascia, 54 significant skeletal irregularities of, 454
- Head, Management of injuries of and spinal cord in army 95; cerebral metabolism in experimental injury of, 00 acute physiological responses in experimental injury of, with special reference to mechanism of death soon after trauma, 00 injury of study of patients with chronic post-traumatic complaints, 70 cavernous sinus thrombosis treated with heparin and sulfathiazole, 358 fractures of sphenoid tripod, 419
- Headache, Post-traumatic and histamine, 3 peroxysmal and postural, from intraventricular cysts and tumors, 342
- Health-plan principles in Kaiser Industries, 33
- Heart, Actinomyces of, simulating rheumatic fever: report of 3 cases of cardiac actinomyces with review of literature, 54 management of delivery in pregnancy complicated by serious rheumatic disease of, 45 angiocardiology: anatomy of, in health and disease, 04, abnormal origin of left coronary artery with extensive cardiac changes in a female child thirteen months old, 04, chronic constrictive pericarditis, partial pericardiectomy and epicardiectomy in 24 cases, 05 rubella early in pregnancy causing congenital malformations of eyes and, 23 wounds of, 348, surgical treatment of cardiac syncope; apparent death, fibrillation of, stoppage of, 349, beneficial effect of intravenous infusions in acute pericardial tamponade, 426
- Heart-extract powder Clinical value of growth-promoting substance in treatment of indolent wounds, 474
- Heat exhaustion, Desert climate; physiological and clinical observations, 240 desert climate, physiological and clinical observations, 240
- Hemangioblastoma, Giant, with thrombocytopenic purpura, 238
- Hemangioma, Of adult and of infant larynx; review of literature and report of 2 cases, 91
- Hemoglobin, Concentration of, in college women, 9
- Hemorrhage, Spontaneous subarachnoid, in infants, its relation to hydrocephalus, 29, leiomyoma of jejunum, intermittent melena of fourteen years' duration, and fatal hemorrhage, 38 uncontrollable, after dissection therapy with autopsy findings, 6 septicemia and purpura with adrenal, in adult (Waterhouse-Friderichsen syndrome) role of adrenal gland in production of syndrome, 8 effect of massive experimental, on hepatic function in dogs, 68, on diagnosis of, in case, study of extensive bleeding in volunteers, 29 rapid replacement of fluid in, and shock, 208 retinal, following transfusion, 389
- Hemostasis, With absorbable gauze (oxidized cellulose), 5 fibrin foam as agent for in rehabilitation neurosurgery 79
- Hemostatic, Study of oxalic acid ex, 388
- Hemothorax, Notes and observations, 428 traumatic; de-corticication in treatment of chronic uninfected type, 428
- Heparin, Thrombophlebitis of cavernous sinus following extraction of teeth cure with penicillin and, 449, cavernous-sinus thrombosis treated with, and sulfathiazole, 358

- Hiccup, Causes of failure in treatment of congenital dislocation of, 209
- Histamine, Headache due to trauma and, 31
- Hodgkin's disease, Intrathoracic, 87 294

- Hormones**, Biochemical effects of sex, acid and alkaline phosphatase activity calcium and phosphorus, 55
Influence of a number of androgenic steroids on urinary excretion of neutral 17-ketosteroids, 164, treatment of amenorrhea with combined anterior pituitary follicle-stimulating, and chorionic gonadotropin, 197, male climacteric: its symptomatology, diagnosis, and treatment, 206 clinical and roentgenological study of effects of therapy with, on bone growth, 244 treatment of prostatic carcinoma by castration and administration of estrogenic, 369 role of iliojudicious endocrine therapy in delayed diagnosis of uterine cancer 439 gonadotropins and antihormone problem 440
- Horn**, Penile, 368
- Hospital**, Reception and evacuation notes on administrative problems arising in large general (1 500 beds) acting as casualty-clearing station, 395
- Hydatidosis**, Interilioabdominal disarticulation for, of pelvic bones, 55 Interilioabdominal disarticulation for of pelvic bones, 56
- Hydrocele**, Renal, subcapsular renal extravasation 126
- Hydrocephalus**, Spontaneous subarachnoid hemorrhage in infants its relation to, 29
- Hydrothorax**, Ovarian fibromas and theca-cell tumors report of 78 cases with reference to production of ascites and (Meigs syndrome) 359
- Hyperinsulinism** treated by subtotal pancreatectomy 267
- Hyperparathyroidism**, with failure to recalcify after removal of parathyroid adenoma, 83
- Hyperpyrexia**, Desert climate physiological and clinical observations, 240
- Hypertension**, 94, surgical treatment of effect of radical (lumbodorsal) splanchnectomy on hypertensive state of 156 patients followed up for from one to five years, 98, nephrectomy for in two-and-one half year-old child with apparent cure for three years, 126, surgical treatment of 343 study by newer renal function tests in unusual case of following irradiation of one kidney relief of patient by nephrectomy 363
- Hyperthyroidism** Use of thiouracil in preparation of patients with, for thyroidectomy 83, thiouracil in medical management of 118 treatment of with thiouracil, 48
- Hypoproteinemia**, Treatment of acute and chronic protein deficiencies collective review 333
- Hysterectomy** Procidencia Chadlin vaginal subtotal, for cure of fourth-degree prolapse review of technique and results, 358
- ILEITIS**, An appraisal of results of surgery in treatment of regional, 437
- Ileocecal valve** Experimental observations on human, 40
- Immobilization**, Alro-lite, new plastic medium for clinical, 306
- Industry** Eye injuries at aircraft plant, 169 health-plan principles in Kaiser 322
- Infections**, Preponderance of gallstones in women collective review 1 thrombosis of cavernous sinus with hemolytic streptococcal bacteremia, treatment by intravenous injection of sulfadiazine and penicillin with recovery 24 severe puerperal fever puerperal fever of 1921 and puerperal fever now 46 effect of ligation of, of patent ductus arteriosus, 60 comparison of various types of local treatment in controlled series of experimental burns in human volunteers, 71 intraperitoneal chemotherapy 72; 2 cases of clostridium welchii, treated with penicillin, 73 bacterial content of air in army barracks results of study with especial reference to dispersion of bacteria by air circulation system, 87 clinical use of penicillin in genitourinary, 150 use of penicillin in surgical, 147 prophylaxis and therapeutics of clostridial, (gas gangrene) 162 surgical manifestations of coccidioidomycosis, 163 re-evaluation of sulfa drugs, 231 treatment of staphylococcal, with penicillin by intermittent sterilization, 231 need for asepsis in local penicillin therapy, 232 study of "penicillin failures", 232 roentgen therapy in gas bacillus, report of 9 cases with recovery 238 penicillin therapy in ocular 250, penicillin pastilles for oral, 251 penicillin special reference to use in, complicating diabetes, 202 use of penicillin in topical application, 302 effects of cooling on, produced experimentally, 320 sulfonamide compounds in treatment of, of nasal sinuses, 330 chemotherapy in intracranial treatment of staphylococcal and pneumococcal meningitis with sulfathiazole and sulfadiazine, 347 in war wounds, 393 use of gauze inoculated with penicillin notatum or impregnated with crude penicillin in treatment of surface infections, 397 use of "sump" drain in peritoneal, 398.
- Infusion**, Effect of intravenous fluids on dehydrated patients and on normal subjects, 156
- Insemination**, Artificial report on 80 cases, 442
- Intervertebral discs**, Clinical analysis of 1,000 consecutive cases of low back pain, with particular reference to sciatic pain caused by extrusion of 29 results of surgical treatment of sciatica due to herniation of, in Canadian soldiers overseas, 94 herniation of nucleus pulposus study of 100 cases treated by operation 179, roentgenographic diagnosis of small central protruded including discussion of use of pantopne as myelographic medium 236 improved retractor for hemilaminectomy 403 brachial pain from herniation of cervical 424
- Intestines**, Diverticula and duplications of 114 case of spontaneous gastrojejunal fistula eight years after an operative gastrojejunostomy 214 Intubation studies of human small review of ten-year experience, 117 bowel surgery: impressions after five years of experience, 194 length of small, 196 primary malignant tumors of small bowel, 263 transplantation of ureters into, 270 aberrant pancreatic and gastric tissue in, 319 rupture of caused by nonpenetrating trauma of abdominal wall report of cases, 351 healing of anastomosis of 352 an appraisal of results of surgery in treatment of regional ileitis, 437 melanoma of small 48
- Iris**, Epithelial tumors of, 169
- Iron**, Observations on some histochemical reactions in human placenta with reference to significance of lipoids, glycogen, and, 362
- Irritation and carcinogenesis**, 245
- JAUNDICE**, Homologous-serum 63
- Jaws**, Recent advances in treatment of carcinoma of mouth and, 27
- Jejunum** Loxomyoma of intermittent melena of fourteen years' duration, and fatal hemorrhage, 38
- Joints**, Interilioabdominal disarticulation for hydatidosis of pelvic bones, 55 interilioabdominal disarticulation for hydatidosis of pelvic bones, 56 observations on battle-casualty compound fractures and injuries of, in middle East, 140 acute manifestations of yaws of bones and,

- 308 pneumococcal arthritis report of case of so-called primary pneumococcal arthritis, 373 congenital subluxation of acromioclavicular 374
- K**aiser Industries, Health-plan principles in, 333
Kaoilin, Processing of plasma with, 61
Kenny method, Evaluation of, in treatment of chronic infantile paralysis, 133
- 17 Ketosteroids, Influence of number of androgenic steroids on urinary excretion of neutral, 64 excretion of, in carcinoma of prostate, personal experiences, 304, estimation of urinary in diagnosis of adrenocortical tumors, 443
- Kidneys, Case report illustrating brief period of time necessary to formation of large staghorn calculus of 40; complications of sulfonamide administrations involving kidney reactions from sulfathiazole and sulfadiazine, 186 hydrocele of subcapsular renal extravasation, 36 renal complications of Reiter's disease, 304, toxic reactions of newer sulfonamides, 330 perirenal inflammation, 68, ectopia of report of 6 cases, 79 transperitoneal fixation of and colon, 353 traumatic uremia, reports on 8 cases, 363 study by newer function tests of in unusual case of hypertension following irradiation of one of relief of patient by nephrectomy 363 acute and chronic symptoms and diagnosis of movable, 363 leiomyoma of associated with hemorrhagic cyst, 364, application of stapling removal of difficult Wilms' tumors, 364 clinical and statistical study of 471 congenital anomalies of, and ureter, 443, congenital solitary: case reports and consideration of military significance, 444 mechanism of renal complications in sulfonamide therapy 444 renal tumors stimulating gastrointestinal disease, 445 malignant renal neoplasm clinical and pathological study 445 classification of tumors of, 484
- King operation, Modification of, for bilateral paralysis of vocal cord, 74
- Knee, Noninjection method for roentgenographic visualization of internal semilunar cartilage, 53 traumatic osteochondritis of patella, 456 internal derangements and fractures involving: results of 5 consecutive arthroplasties performed at station hospital, 453
- Knots, True, of umbilical cord, 303
- L**abor, Use of methergine (synthetic ergonovine) in third stage of 44 management of delivery in pregnancy complicated by serious rheumatic heart disease, 45 cesarean-section morbidity and septic mortality in relation to type of operation, 45 contracted pelvis in childbirth, study of its morbid effects on mother and child, 13 methergine (synthetic lyseric-acid derivative) new oxytocic; preliminary report, 3 childbirth in Greek island of Chios in Sixth Century B C 5 comparison between surgical induction of, by means of the rectal tube and surgical induction of, by artificial rupture of membranes, statistical survey 30 placenta previa, report of 70 cases, 375 evaluation of continuous caudal analgesia, 303 comparative analysis of drugs in continuous caudal analgesia, 304 report on 130 consecutive cases of placenta previa without maternal death, 36 continuous caudal analgesia; interim report, 40 sodium-pentothal anesthesia in obstetrics, 403
- Lactation, Inhibition of by hexestrol dipropionate, 14
- Lantornis pericraniocephaloplasty for congenital dorsal subluxation or congenital overlap of fifth toe, 308
- Laryngectomy Total, simplified techniques with use of special clamp which makes possible removal of larynx and pre-epiglottic space without opening of pharynx, 35
- Larynx, What can we do for myasthenia of 91 hemangioma of adult and of infant, review of literature and report of cases, 9 epithelioma of, 93, carcinoma of, review of treatment and end-results at Brooklyn Cancer Institute, 9 pre-epiglottic space its relation to carcinoma of epiglottis, 74, cystadenoma of report of 4 cases, 340; paralysis of an early sign of recurrence following radical mastectomy for carcinoma, with report of 6 cases, 431
- Leg, Ambulatory treatment of fractures of lower extremities, 1 muscle hernias of leg: review of literature; report of cases, 375 growth arrest for equalizing lengths of 379 practical points in plaster technique; two years of experience in forward surgery with Royal Army Medical Corps (mobile) casualty-clearing station, 941-943, 38 anatomic and physiological considerations in alignment and fitting of amputation prostheses for lower extremity 454
- Leiomyoma, Of jejunum intermittent melena of fourteen years' duration, and fatal hemorrhage, 38 of kidney associated with hemorrhagic cyst, 364
- Lenses, Case of polycythemia vera, extraction of both, with satisfactory result, 69 localization of intraocular foreign bodies by means of contact, 349
- Leontiasis ossea complicated by Marjolin's ulcer 73
- Leucemia, Mesenteric thromboses in lymphatic, treated with dicumarol, 36 clinical significance of deeper anatomic changes in lymphoid diseases, 64, born trauma precipitating acute, or leucemoid condition, 330
- Lipids, Observations on some histochemical reactions to human placenta with reference to significance of glycogen, iron, and, 36
- Lips, Closure of defects of with composite revision border-defined flaps, 67
- Liver Abscess of unsuspected until perforation, 39 cancer of in negro in Africa and America, 39, necrosis of in burns treated with tannic acid, 146, effect of massive experimental hemorrhage on function of, in dogs, 68 clinical features of primary carcinoma of, 366
- Lobectomy Lobar collapse after 93
- Lungs, Closed intrapleural pneumomolysis, 5 closed intrapleural pneumolysis, 33 late results of closed intrapleural pneumolysis, 33 experiences in treatment of bronchial cancer 80 arteriovenous fistula of, 91 postlobectomy lobar collapse, 93 muscle-splitting thoracoplasty 3 bilateral thoracoplasty 93 radioactivity and cancer of a critical review of cancer of, in miners of Schneeberg and Joachimthal, 1 3 synopsis of review of literature and analysis of 69 cases, 8 1 chest complications after gastric surgery 9 irradiation pneumonitis; report of case, 303 pulmonary disease associated with megasophagus, 571 spontaneous lobectomy 57 prognosis after successful pneumonectomy 58 congenital absence of, (agenesis) and other anomalies of tracheobronchial tree, 59 pulmonary suppuration secondary to carliomphosis, 345 hydatid cysts of, 345 present status of surgical treatment of primary carcinoma of 347, traumatic hemothorax decortication in treatment of chronic uninfected type, 458 sulfonamide therapy in clean thoracoplasty cases, 459

- Lymphedema, Congenital hereditary (Milroy's disease) 138

- Operations, Blood loss in surgical, chairman's address, 60, acute starvation following, or injury with special reference to caloric and protein needs, 144
- Ophthalmology Penicillin in, 250
- Orchiectomy Experience with, for carcinoma of prostate, 368 bilateral, for carcinoma of prostate gland, 369, early or late, for carcinoma of prostate, 437
- Oesophagus, Implant of substitute for autogenous esophagus, 284
- Osteitis fibrosa cystica, Severe, with parathyroid tumor report of case of fifteen years' duration, 39
- Osteochondritis, Traumatic, of patella, 456
- Osteomalacia, Calcium and phosphorus metabolism in; availability of inorganic pyridine, and dietary phosphorus and effect of vitamin D 434
- Osteomyelitis, Polyarticular arthritis and, due to proteases inguinal, 54 treatment of, of facial bones 114 penicillin, 73 of frontal bone treated with penicillin, 95 prognosis in acute hematogenous, with and without chemotherapy 28, clinical diagnosis, prognosis, and treatment of acute hematogenous, 453
- Otitis externa in New Guinea, 90
- Otitis media, Treatment of chronic suppurative, by local application of penicillin and other drugs, 90; conservative treatment of chronic suppurative, in adults, 5
- Otorrhea, Treatment of otorrhea and, 26
- Ototoxicity, Surgical treatment of, 25 pregnancy and, 44
- Ovaries, Torsion of cysts of in children, 421 hydrotidosis mole of 20 new treatment for microcystic, by use of diethylstilbestrol five-year study 272 cyclic changes of in artificial vaginal mucosa, 273 relationship of granulosa-cell tumors of to endometrial carcinoma, 358, fibrosarcoma of and theca-cell tumors, report of 28 cases with reference to production of sacitis and hydrothorax (Meigs' syndrome) 359 course of pregnancy following total ablation of 361
- Ovary Full-term pregnancy after removal of remaining, at five months of gestation, 47
- Oxalic acid, Study of, as hemostatic, 388
- Oxygen, Utilization of by brain in traumatic shock, 167 protective effects of preoxygenation on abdominal gas pains, results of study of preflight breathing of, on pain resulting from decompression to 38,000 feet, 407
- PAGET'S disease; its pathological physiology and importance of this in complications arising from fracture and immobilization, 3

- Pain.** Clinical analysis of 1,000 consecutive cases of low back, with reference to sciatic, caused by extrusion of intervertebral disc, 29. roentgen analysis of motion of lower lumbar vertebrae in normal individuals and in patients with low back, 237. protective effects of preoxygenation on abdominal gas results of study of prelight breathing of oxygen on, resulting from decompression to 38,000 feet, 407
- Pancreas.** Surgical treatment of carcinoma of body of 117. aberrant tissue of and stomach in intestinal tract, 319. biliary lithiasis and disease of contribution on operative cholangiography 355. case of accessory in unusual position complicated by acute necrosis, 355, physiological observations on patients with external fistula of 356. radical pancreaticoduodenal resection for adenocarcinoma of head of, 356. rupture of, 438
- Pancreatotomy.** Hyperinsulinism treated by subtotal, 267
- Pancreatitis.** Conservative management of acute, 116
- Pantopaque.** 235. Roentgenographic diagnosis of small central protruded intervertebral disc including discussion of use of as myelographic medium, 356
- Paralysis.** Evaluation of Kenny method in treatment of chronic infantile, 133. modification of Kling operation for bilateral, of vocal cord, 174. significance of muscle spasm in acute stage of infantile, based on action-current records, 288. epidemiology of poliomyelitis, 330
- Parathyroid glands.** Hyperparathyroidism, with failure to recalcify after removal of adenoma from 83. severe osteitis fibrosa cystica with tumor of report of case of fifteen years' duration, 319
- Paramecin.** Treatment of acute and chronic protein deficiencies collective review 323
- Patella.** Traumatic osteochondritis of 456
- Perlin.** Intravenous solution of, in prophylaxis and treatment of shock, 71. evaluation of gelatin and solutions of, as substitutes for plasma in treatment of shock. histological changes produced in human beings, 467
- Pellegri-Stieda disease** in Bantu 375
- Pelvis.** Interillobdominal disarticulation for hydatidosis of bones of 55. interillobdominal disarticulation for hydatidosis of bones of 56. contracted, in childbirth study of its morbid effects on mother and child, 121. clinically suspect, and its radiographical investigation in 1,000 cases, 152. urinary complications of endometriosis of 282. value of periodic examination of, in control of cancer of uterus, 358
- Pencilin.** In treatment of cavernous-sinus thrombophlebitis recovery with unilateral ascending optic atrophy 24. in acute empyema, 34. treatment of sulfonamide-resistant gonorrhea with, 51. one-day treatment of sulfonamide-resistant acute gonorrhea with, 52. use of, for gonorrhea resistant to sulfonamide compounds, report of 450 cases, 52. treatment of osteomyelitis of facial bones with, 73. in battle casualties, 73. 2 cases of clostridium welchii infection treated with, 73. treatment of chronic suppurative otitis media by local application of and other drugs, 90. osteomyelitis of frontal bone treated with, 90. clinical use of in genitourinary infections, 130. in treatment of granuloma inguinale, 130. use of, in surgical infections, 147. inactivation of by serum, 149. use of in diseases of ear 170. uses of, in diseases of nose and throat, 171. treatment of meningococcal meningitis with, 178. for treatment of chemoresistant gonorrhea in female 198. in prevention and treatment of congenital syphilis, 203. treatment of staphylococcal infections with, by
- Intermittent sterilization, 231. treatment of multiple furunculosis with, 251. need for asepsis in local therapy with, 252. allergy to 252. study of failures of 253. thrombophlebitis of cavernous sinus following extraction of teeth cure with and heparin, 249. in ophthalmology 250. therapy in ocular infections, 250. pastilles of for oral infections, 252. in prevention of postoperative empyema, 258. in sulfonamide-resistant gonorrhea, 281. special reference to use in infections complicating diabetes, 302. use of, in topical application, 302. treatment of human anthrax with, 303. micro-methods of estimating, in blood serum and other body fluids, 319. therapy in ophthalmology with, 359. treatment of sulfonamide-resistant gonorrhea with results of multiple and single infection methods, 371. 233. cases of sulf-resistant gonorrhea treated with 50,000 units of 372. effect of para-aminobiphenyl acid on plasma concentration of in man, 389. content of in blood serum after various doses of, given by various routes, 397. use of gauze inoculated with notatum or impregnated with crude, in treatment of surface infections, 397. use of in treatment of peritonitis, 398. gas gangrene collective review 411. cavernous-sinus thrombosis treated with, 419. in treatment of surgical infections of central nervous system, 424. wound treatment by delayed suture, 473. tetanus, report of 2 cases treated with, 475. studies on common pathogenic fungi and on actinomyces bovis, in vitro effect of fatty acids in vitro effect of sulfonamides in vitro effect of, 479. temporary character of "fastness" of staphylococci to, 480
- Penicillin X,** 301
- Penicillium notatum.** Use of gauze inoculated with, or impregnated with crude penicillin in treatment of surface infections, 397
- Penis.** Horn of 368
- Pentothal.** Four hundred and ten cases of goiter under general anesthesia with, 74
- Pentothal sodium.** Intravenous anesthesia with, in peace and war 74
- Pericardiotomy.** Indications for with special reference to exposure of infected patent ductus, 184
- Pericarditis.** Chronic constrictive partial pericardectomy and epicardialysis in 24 cases, 105
- Peripheral nerves.** Prognosis of injuries of, 93. personal experience of exploration and re-exploration of injured nerves, 95. motor-nerve function with lesions of; a quantitative study 176. nerve degeneration following prolonged cooling of extremity 254
- Peritoneoscopy.** Economic value of 431
- Peritoneum.** Use of sump drain in infection of 398
- Peritonitis.** Roentgen features of chronic tuberculous, 77. use of penicillin in treatment of 398
- Perspiration.** Rate of insensible, (diffusion of water) locally through living and through dead human skin 313
- Pharyngoplasty.** Total, 91
- Pharynx.** Tuberculosis of nasopharynx, 174
- Phlebotasia and phlebothrombosis of brain in newborn and early childhood, 177**
- Phlebothrombosis.** Phlebotasia and, of brain in newborn and early childhood, 177
- Phosphatase.** Biochemical effects of sex hormones acid and alkaline activity with regard to calcium and phosphorus, 53
- Phosphorus.** Hematological complications of therapy with radioactive, 155

- Phytin, Calcium and phosphorus metabolism in osteomalacia: variability of inorganic, and dietary phosphorus and effect of vitamin D 284
- Pilonidal cysts, 298 analysis of 132 consecutive cases, 395
- Pilonidal sinus, Clinical experiences with Rogers operation in 35 consecutive cases, 25
- Placenta, Determination of site of, in bleeding during last trimester of pregnancy 78 isolation of as diagnostic criterion of maternal toxemia, 275 observations on some histochemical reactions in human, with reference to significance of lipoids, glycogen, iron, 363
- Placenta previa, Report of 70 cases, 275 report on 130 consecutive cases of without maternal death, 361 study of 250 cases of 44
- Plasma, Processing of with kaolin, 6 increases in volume of following administration of sodium salts, 61 "suture" of wounds by adhesion due to the use of 67 skin-graft fixation by adhesion with, 217 volume in traumatic shock, 25 clot suture of nerves with autologous use in clinical surgery 54 clinical use of products of fractionation of human use of products of fibrinogen and thrombin in surgery 293 gelatin as substitute for: observations on administration to human beings, 294 total disruption of surgical wounds of abdominal wall reference to protenemia and ascorbic acid of 299 treatment of acute and chronic protein deficiencies, collective review 33 effect of para-aminobiphenyl acid on concentration of penicillin in, of man, 389 use of specially prepared gelatin solution as substitute for 389 evaluation of gelatin and pectin solutions as substitutes for in treatment of shock histological changes produced in human beings, 467 modification of fixation method with, (Sano) of skin grafting by use of bobbinet and mirror attachment, 471
- Plasmapheresis, Experimental shock effects of acute, in healthy dogs, 85

- of 9 cases including 2 cases of coexisting carcinoma and, 425 prophylactic use of pneumoperitoneum in pericrurion of patients with, 441
- Tumors, Racial and sexual incidence of primary intracranial** statistical study of 133 cases verified by autopsy 30 multiple primary malignant and susceptibility to cancer 83 surgical treatment and clinical manifestations of benign, of esophagus with report of 7 cases, 113 volume localization of deep-seated, by means of tomography, 155 epithelial of iris, 169; malignant, of nasal cavity report of 8 cases in which frontoethmoid approach was employed, 172 primary of Stensen's and Wharton's ducts, 173 mode of origin of solitary localized squamous-cell growths of skin, 245 primary malignant, of small bowel 263 Boeck's sarcoma, 315; sarcoidosis of Boeck, 315 paroxysmal and postural headaches from intraventricular cysts and 347 of Vater's ampulla duodenopancreatotomy in one stage, 355 relationship of granulosa-cell of ovary to endometrial carcinoma, 358 ovarian fibromas and theca-cell report of 78 cases with reference to production of ascites and hydrothorax (Meigs syndrome) 359 chemical treatment of reactions of 4 patients with advanced malignant, to injection of polyanthracene from *Serratia marcescens* culture filtrate 408 estimation of urinary 17-ketosteroids in diagnosis of adrenocortical, 443 renal, stimulating gastrointestinal disease, 443 malignant renal clinical and pathological study 445 conservative surgery in certain benign, of ureter 445 classification of of kidney 484
- Tuberculosis, Surgery in, 223**
- Typhus fever** Surgical complications of 161
- ULCER**, Visualization of rubber tip of gastroscope differentiation from gastric, 40 subtotal gastrectomy for duodenal, 114; complications and mortality in subtotal gastrectomy for duodenal report of two-stage procedure, 191 gastric carcinoma, observations on peptic, and healing, 261 acute perforated, in West Scotland, 262 acute perforated peptic, in West Scotland, 263 tropical 301 rodent, treated by application of sodium bicarbonate, 314 perforated, of esophagus following burn, 349 peptic, in Canadian army (1940 to 1944) 351 gastroscopic control of treatment of gastric, by duodenal feeding, 432 peptic study of number of cases treated in Western Infirmary of Glasgow during forty-six years (1897 to 1942) 433 discussion on treatment of duodenal, 434 problem of peptic, in army, 468 critique of gastroscopy 475 Curling's, in experimental burn, 485
- Ulna**, Traumatic synostosis of distal third of radius and, 55
- Umbilical cord**, True knots of 201
- Uremia**, Extrarenal report of 3 cases due to pyloric obstruction, 188 traumatic reports on 8 cases, 363
- Ureter** Supernumerary with extravascular orifice, 127 transplantation of new procedure, 127 nonfibrous vesicoureteral obstruction, 129 pregnancy after bilateral lateral transplantation of report of case after bilateral ureterocutaneous transplantation, 200 transplantation of, into bowel, 270 primary carcinoma of treated by excision and anastomosis of cut ends, 364 analysis of 90 cases of transplantation of for obstetrical vesicovaginal fistula, 366 clinical and statistical study of congenital anomalies of kidney and, 443 calculus of, treated by reversed catheterization, 445 conservative surgery in certain benign tumors of 445
- Urethra**, Treatment of inflammatory strictures of 50 traumatic rupture of and bladder 366 war wounds of 459
- Urinary Tract**, Supernumerary ureter with extravascular orifice, 127 ureterocutaneous transplantation new procedure, 127 injuries of urinary bladder 129, nonfibrous vesicoureteral obstruction, 129 subtotal peritoneal prostaticectomy presentation of new technique, 203 studies concerning effects of calcium on 207 sterile pyuria, 281 complications of pelvic endometriosis in, 282 pyelocystostomy report of 2 cases, 448
- Uterus**, Study of endometrial pattern before and after treatment for amenorrhea, 42 measurement of cyclic variations in quantity of cervical mucus and its correlation with basal temperature, 119 use of diethyl stilbestrol to control bleeding of 119 simple office test for diagnosis of cancer of 119 observations on chronic endometritis, 270 place of surgery in fibroids of, 270 minimal histological changes in biopsies to justify diagnosis of cervical cancer 270 pathology of malignant neoplasm of cervix coincident with pregnancy 271 cancer of cervix of 1930-1942 271; proclitica Chaffin vaginal subtotal hysterectomy for cure of fourth-degree prolapse review of technique and results, 358 value of periodic pelvic examination in control of cancer of 358 relationship of granulosa-cell tumors of ovary to endometrial carcinoma, 358 immediate and later results of Wertheim-Schauta operation, 358 conization and early diagnosis of carcinoma of cervix, 439 role of injudicious endocrine therapy in delayed diagnosis of cancer of 439
- VAGINA**, Cytology of in premature puberty 197 cyclic ovarian changes in mucosa of artificial, 273
- Varices**, Veins with anatomic findings and operative procedure based upon them 290 value of venography in veins with, 384
- Vater** Tumor of ampulla of duodenopancreatotomy in one stage, 355
- Veins**, Obstruction of hepatic (Chiari's disease) report of 5 cases, 195 varicose anatomic findings and operative procedure based upon them, 290 value of venography in varicose, 384
- Venography** Value of in varicose veins, 384
- Vertebrae**, Roentgen analysis of motion of lower lumbar in normal individuals and in patients with low back pain, 237 internal fixation for lumbosacral fusion, 377 dilatation of canal of associated with congenital anomalies of spinal cord, 423 congenital stricture of spinal canal, 454 surgical and anatomic significance of mammillary tubercle of last thoracic, 455
- Vitamins**, Vitamin C-sulfonamide compounds in healing of wounds use of sulfanilamide ascorbate in treatment of chronic suppuration of wound after radical mastoidectomy 26 study of vitamin C saturation in hospital children, 160 vitamin C economy in human subject, 312, note on minimum requirements of man for vitamin C and certain other 406; relationship between clinical picture of mild or early deficiency of and laboratory determinations of levels of 406
- Vocal cord**, Modification of King operation for bilateral paralysis of, 174
- Volkman's contracture**, Ischemic nerve lesions occurring in, 422
- Vulva**, Intraepidermal carcinoma (Bowen's disease) of report of 3 cases, 197
- Vulvovaginitis**, Treatment of gonococcal, 439

WAR, Progress of aviation otology in World, 35; injury to ears among battle casualties of western desert, 35 comparative report on ear nose and throat work in army at home and overseas, 35, early diagnosis of peripheral nerve injuries in battle casualties, 38 major complications of penetrating wounds of chest, 38 evacuation of fractured femur Tobruk plaster and other methods used in Middle East, 57 wounds of abdomen report of 64 cases treated by laparotomy 65 gas gangrene at Australian general hospital in Owen Stanley and Buna-Gona campaign, 65 blood transfusion during battle of Mareth with special reference to problems of supply 65 surgery in Royal Air Force, 66 penicillin in battle casualties, 73 penitonal-sodium intra venous anesthesia in peace and, 74 vascular injuries of 134, delayed suture of soft tissue wounds, 130 abdominal surgery in forward areas observations made in casualty-clearing station, 141 1943, 140 observations on battle-casualty compound fractures and joint injuries in Middle East, 140 surgical management of wounded in Mediterranean theater at time of fall of Rome, 14 moni-injection method for roentgenographic visualization of internal semilunar cartilage, 135 conservative treatment of abdominal wounds, 13 experiences with mobile surgical team on amphibious operation in New Guinea, 224, physiological effects of drinking undiluted sea water 241 foot strains in services, 289, analysis of 350 flying-bomb casualties, 305 secondary suture of wounds of, 306, medical problems in amphibious war fare landing ship tank in evacuation of casualties, 306 tropical ulcer, 301, nutrition and diet in time of, 3 or giant magnet in ophthalmic battle casualties, 338 peptic ulcer in Canadian army (1940-1944) 335 practical points in plaster technique two years of experience in forward surgery with Royal Army Medical Corps (mobile) casualty-clearing station, 34 1943, 35 underwater blast injuries of abdomen, 305, infection in wounds of 305 gas gangrene in amphibious warfare in Pacific area, 304 evacuation of casualties from beach-head, 305 reception and evacuation notes on administrative problems arising in large general hospital (500 beds) acting as casualty-clearing station, 305 physical fitness tests for convalescents, 306 experiences with anesthesia in combat areas, 403 protective effects of preoxygenation on abdominal gas pain results of study of preflight breathing of oxygen on pain resulting from decompression to 38,000 feet, 407 acute high-altitude anoxia, gross and histological observations in 7 cases, 407 gas gangrene: collective review 411 rupture of pancreas, 418 congenital solitary kidney case reports and consideration of military significance, 444 wounds of urethra in, 450 army amputation program, 460 internal derangements and fractures involving knee: results of 30 consecutive arthroplasties performed at station hospital, 465 cause,

effect and treatment of air-blast injuries, 468 peptic ulcer problem in army, 468 some experience with reparative surgery in Middle East, 469 treatment of fractures in combat area, 469 surgery in airborne divisions, 469 wound treatment by delayed suture, 473

Water, Physiological effects of drinking undiluted sea, 241 differential roles of layers of human epigastric skin on diffusion rate of, 31 rate of isosmotic perspiration (diffusion of) locally through living and through dead human skin, 33

Waterhouse-Friderichsen syndrome, Septicemia and purpura with adrenal hemorrhage in adult role of adrenal gland in production of syndrome, 81 meningococcal-adrenal syndrome: 5 cases with 1 recovery 451

Wertheim-Schauta operation, Immediate and later results of 358

Wharton duct, Primary tumors of Stensen's duct and, 175

Wilms tumor, Application of staging removal of difficult, 564

Wounds, Vitamin C-sulfonamide compounds in healing of use of sulfanilamide ascorbate in treatment of chronic suppuration of, after radical mastectomy 26; war, of abdomen, report of 64 cases treated by laparotomy 65 suture of, by plasma thrombin adhesion, 67 grease-gun injuries, 71 role of allergy in delayed healing and disruption of, 86 absorption of sulfathiazole from, 85 experimental study of lateral spread of epidermoid (squamous-cell) carcinoma in man, and reaction of such lesion to stimulus for healing of, 87 delayed suture of soft-tissue, 30 local sulfanilamide treatment of fresh, in complete plasters, 145; treatment of burns and, with skin loss by envelope method, 46 late closure of 147, conservative treatment of abdominal, 3 effect of sulfonamides upon experimental gunshot, involving peripheral nerve, 151 analysis of 50 flying-bomb casualties, 305 secondary suture of war 306, total disruption of surgical, of abdominal wall, with reference to plasmon protolysis and plasma ascorbic acid, 209 healing of surface cutaneous analogy with healing of superficial burns, 300 effects of sulfanilamide locally implanted in clean, 30 effect of cooling on healing of, 320 of heart, 348, infection in war 305 war of urethra, 450 treatment of by delayed suture, 473 clinical value of growth-promoting substance in treatment of lacerated, 474 healing of experimental study of water-soluble chlorophyll derivates in conjunction with various antibacterial agents, 485

YAWS, Acute manifestations of, of bones and joints, 268

ZOVDER, Simplified treatment of secondary amenorrhea according to, 43
